AN EXPERIMENTAL STUDY IN WOUND HEALING IN VITAMIN C DEPLETED HUMAN SUBJECTS

JOHN A. WOLFER M.D. F.A.C.S., CHESTER J. FARMER M.A.

WALTER W. CARROLL, M.S. M.D. DONALD O. MANSHARDT M.D. Chicago, Illinois

THE study of wound healing has been the subject of much thought through the ages but it is only in recent years that surgeons have become acquainted with tangible evidence concerning the value of certain systemically acting biochemical factors. Both clinical and laboratory observations have shown conclusively that the rate and efficiency of primary wound healing depend to a great extent upon the vitamin C (ascorbic acid) content and the protein concentration in the tissues while to a lesser degree upon carbohydrate and some mineral metabolism. Such conclusions have been drawn by eliminating the well known local deterrent factors of wound healing. There has been satisfactory laboratory evidence cited in the literature to prove the rôle played by vitamin C

through animal experimentation but the data obtained from clinical observations have been of necessity impure and incomplete. By this we mean that a condition in which there is a deficiency of a single vitamin as the only factor (pure monavitaminosis) is a rarity whereas the usual instance is that of a patient presenting a poor nutritional status with multiple avitaminoses, a depletion in serum proteins and a distorted metabolism. Thus the early observations on impaired wound healing dealt with multiple deficiencies (2, 8, 16, 22, 25, 27, 28), and it was eventually necessary to use animal experimentation to differentiate the factors which were due to hypoproteinemia and those due to a vitamin C deficiency.

There has been some thought that the part played by vitamin C in human wound healing is overshadowed in importance by other mechanisms on the assumption that the human

The experimental work described here is part of an investigation conducted under a contract recommended by the Committee on Medical Research between the Office of Scientific Research and Development and Northwestern University.

factor is such that the tissue content not be sufficiently reduced. Concerning this, we must remember that the human skin cannot synthesize vitamin C. Thus, the healing of a wound is something of an emergency; it is logical to expect replacement of necessary substances in the body to be mobilized on the demand of a healing wound.

The work of Lauber and Rosenfeld indicated that in animals on a scorbutic diet any organs lost their vitamin C after they had been wounded while vitamin C could be demonstrated in the tissues about the healing wound. Despite this finding of a chemical balance the same kind of experimentation has revealed a relationship in tensile strength of the healing wound in those rendered scorbutic. Bartlett (1942) found the tensile strength to be proportionate to the vitamin C content of the scar tissue tested.

It is work as just referred to should not lull a sense of false security because even the tissues in greatest need of vitamin C receive top priority in order to obtain satisfactory healing. It may be inferred that all parts of the body suffer proportionately in absence. Workers in this field have found that in the human subject some signs of scurvy can be obtained after 4 weeks of a strict deficiency diet, while 6 weeks of abstinence produces further changes. The total daily intake of vitamin C and the duration of inadequate intake are important in developing symptoms, and it has been found with the aid of guinea pig experiments that changes effected by a complete deficiency diet of short duration can be repeated in humans by administration of a standard dose over long periods of time. It is logical to conclude that the effect of deficiency in wound healing may be widespread in our population than was previously suspected. To our knowledge this study (9-10) on wound healing in completely deficient in vitamin C for a period of months has not been duplicated in this report. In that instance the subject had been on a diet completely deficient in vitamin C for 3 months, and after the plasma vitamin C had been nil for 44 days, biopsy

material from a small wound showed satisfactory healing on the tenth postoperative day. The usual criteria of abundant intercellular substances and capillary formation were used as histological evidence of healing. In the same individual after 6 months on the deficient diet a similar wound showed no signs of healing as evidenced by a lack of intercellular substances and the presence under the skin of an unorganized blood clot. No study of tensile strength was carried out in this individual. While this experiment was of great value the status of the wound never was fully established for according to Hunt there may be a good supply of intercellular fibers present in a healing wound, nevertheless if most of them are made up of immature collagen the tensile strength will be quite low.

An opportunity was afforded us to study the effect on wound healing of a prolonged vitamin C deficiency in 9 otherwise normal healthy young males. In addition 5 normal healthy young males were available as controls. Twelve of these men already have been referred to in a previous abstract (13). Each subject was a medical student who volunteered to submit to a diet deficient in vitamin C for a period of 7 months. The diet was selected from a hospital cafeteria, the foods chosen being free from vitamin C or subjected to processes destructive to vitamin C such as overcooking with or without soda, or by being held on the steam table. Chemical analysis of the whole meals, as well as in individual articles of the diet showed vitamin C to be very low occasionally 5 to 10 milligrams per day or entirely lacking. In this respect our dietetic approach differed from that of Crandon, Lund and Dill (9-10) since a civilian might conceivably select a diet similar to ours, but never as severe as that prescribed by the former investigators. Observations were made on the plasma and white-cell platelet vitamin C content, urinary vitamin C excretion, complete blood chemistry, hemoglobin determination and blood cell count, and metabolic urinary constituents. The deficiency status of the experimental subjects was established and maintained throughout the period of observation. At the

end of this time, an incision was made in the thigh through the skin and fascia and the course of the wound healing studied by removal of biopsy specimens at intervals of 4 to 14 days. This included a measurement of tensile strength of the healing incisions as well as histological examinations of skin and fascia wounds. Immediately after taking the biopsy specimen saturation tests were done to establish the fact that the tissues of the subjects on the deficiency diets were relatively highly depleted of vitamin C.

DEFICIENCY STATUS

As stated, no attempt was made to place our experimental subjects on as rigorous a dietary regimen as carried out by Crandon. We were interested in the effect of a diet grossly inadequate in ascorbic acid when administered over a prolonged period upon the severity of depletion of the body vitamin C and the degree of healing occurring following standardized surgical technique on depleted and undepleted control subjects. We wished to answer the question as to how severe vitamin C depletion must become before marked impairment of the healing process occurred.

All subjects were placed upon a basal diet, adequate in protein, fat, and carbohydrate but as low in vitamin C as selection and preparation could render it. This diet was also somewhat low in the members of the vitamin B complex, but not to such a degree as to be considered deficient. Subjects subsisting on this basal diet were designated for practical purposes as vitamin C deficient. A few of these subjects received daily supplements of the members of the B complex in amounts recommended as adequate by the Committee on Food and Nutrition of the National Research Council. The normal control group was placed upon the basal diet supplemented with adequate amounts of the vitamins of the B complex and 75 to 150 milligrams of ascorbic acid daily.

Several methods have been proposed for ascertaining the degree of depletion of vitamin C suffered by the body tissues. These tests frequently referred to as saturation tests, may be classified according to tech-

nique employed into the following four groups:

1. Measurement of the 24 hour urinary excretion of vitamin C after the oral administration of a standard test dose (1)

2. Measurement of the plasma vitamin C rise and urinary excretion after oral administration of a test dose (12-24)

3. The estimation of the rate of plasma vitamin C drop and urinary excretion in 5 hours following the intravenous administration of a test dose (20-29)

4. The estimation of the vitamin C content of the white-cell platelet layer may also be used as an index of tissue depletion (6)

Of these tests the degree of tissue depletion may most readily be determined by the ad-

Fig. 15. Urinary excretion during 5 hour saturation

uation of a standard oral dose of 15 of vitamin C per kilogram of body and the determination of the blood and urinary vitamin C each hour for ours. The subject empties his bladder and first sample of blood is taken. The test e of vitamin C dissolved in 200 cubic centimeters of water and slightly sweetened if de-a is taken immediately. Blood samples, n either the finger or vein are taken hourly reafter for 5 hours. The bladder is com- pletely emptied at the time the blood samples taken. Both blood and urine samples are lyzed (11) and the data plotted as shown he accompanying charts (Figs. 15 16 17

t is desirable that the saturation test be on the subject in the fasting state. If not ment it may be started 4 hours after a meal which contains no vitamin C. No d is taken during the test. The subject is a total of 400 cubic centimeters of as desired to assure sufficient urine for specimens.

Fig. 6. Magnitude of plasma ascorbic acid rise following saturation test dose of 5 milligrams per kilogram body weight. Data plotted is peak plasma value minus fasting level.

White-cell platelet vitamin C was determined periodically during the investigation. The average values for subjects deprived of vitamin C at the time the surgical studies were done were 0.75 milligram per 100 grams white-cell platelet layer the normal controls averaged 31.85 milligrams per 100.

The plasma total protein levels of all subjects ranged between 6.80 and 7.57 grams per 100 cubic centimeters during the entire study.

SURGICAL PROCEDURE

The left thigh was used throughout. A 6 centimeter longitudinal incision was made over the region in which the fascia lata was suspected of being strongest. The incision first was made through the skin and superficial portion of the subcutaneous layer thus allowing uniform undermining of the skin 1 centimeter away from the incision in each direction. The incision was then continued to the level of the fascia lata, this being carefully exposed with a minimal of tissue damage. A corresponding 6 centimeter longitudinal incision was then made in the fascia, the edges being allowed to fall apart. Interrupted silk

Fig. 17. Vitamin C saturation test. C deficient. November 8, 1942. Weight 63.6 kilograms, dose 954 milligrams, ascorbic acid.

sutures were used for closure of both fascia and skin and were placed about 1 centimeter apart so as to obtain perfect apposition. Simple dressings were then applied. During the course of healing alternate sutures were removed on the fourth day, and the remaining on the sixth or seventh day.

In obtaining the skin specimens for study, two different techniques were used. In 4 cases a 2 centimeter square block was removed so as to include the suture line in its middle. The closure of the defect was obtained by converting this square into a transverse ellipse undermining the borders and using interrupted silk sutures under some tension. This, with the former incision, resulted in a cruciate closure with a maximum of interference to the blood supply. In the remaining 10 cases the original incision was removed in its entirety by an elliptical excision the closure being accomplished with a minimum of undermining and with interrupted silk sutures under only moderate tension.

In all cases the specimens of fascia lata were obtained by simple excision of a corresponding 2 centimeter square section of tissue, which included the suture line. No attempt was made to close this defect.

As a routine, all the subjects were admitted to the hospital the evening before the

Fig. 18. Vitamin C saturation test—control. November 11, 1942. Weight, 89.8 kilograms. Dose 1350 milligrams ascorbic acid.

surgical procedure and remained in the hospital for at least 24 hours afterward. Hospitalization was continued much longer in those exceptional cases in which complications developed. All the surgery was carried out in the operating rooms under strict aseptic precautions the skin preparation being soap and water cleansing for 10 minutes. Exceptions to the latter were made in the secondary operations in those instances in which it was thought that the mechanical rubbing would be deleterious to the wound edges. Routine iodine and alcohol preparation was used in these cases. The anesthetic agent was 1 per cent procaine solution with adrenalin used as a circumferential field block.

The rupture factor. The tensiometer used for the tissue tensile strength determination is shown in Figure 14. The essential feature of this device was a perfectly balanced pair of clamps, which could be separated very slowly by an accurately measured weight of water. The biopsy specimen was held by the soft rubber-cushioned clamps so that the suture line was immediately between and parallel to the clamps. The weight of the clamps was first balanced out and then water was allowed

strength of the suture line of the skin and of the fascia was reduced 19 per cent and 50 per cent, respectively. A study of the saturation tests for these subjects reveals that both con-

trols were adequately supplied with ascorbic acid while one of the two deficient subjects (No 5) previously referred to as having a rupture factor approaching the control aver-

Fig. 10. Comparison of averaged rupture factors of skin of deficient and control groups.

used on the Zenker fixed material. In all, 180 slides were studied. These were graded on an arbitrary scale from 0 to +++ for each component studied, 0 being considered a negative amount, † the minimal amount, and +++ the maximum amount in the series. (Numberical values: 0 † = 0.5, † = 1, † + = 2 and † + + = 3.) While admitting the limitation of this method of grading it offers a means of comparing the slides of the biopsy specimens in relation to each other. This is recorded in Table II.

In all cases, healing in the skin was first evidenced by a proliferation of fibroblasts just beneath the epithelium while in the fascium, healing generally occurred by a growth of granulation tissue into the wound from the inner and outer surfaces of the fascium. The reticulum stain was expected to be a more sensitive indicator of incisional sub-stances in the earlier stages of healing however this did not prove to be true in all in-

stances. Subject No. 1 (D.A.) showed the presence of collagen after 4 days of healing with no evidence of reticulum. This discrepancy may be the result of taking the section stained for collagen and the section stained for reticulum from separate blocks of tissue. In general, the amount of reticulum paralleled the amount of collagen, slightly more reticulum being evident in the earlier stages of healing and slightly less in the later stages (Fig. 21). In comparing the tensile strength with the degree of ascorbic acid deficiency as measured by the saturation tests and tissue depletion determinations, three clear-cut time intervals are available for study. The first is that of the fifth day and is represented by the deficient subject No. 2 (G.H.) and the control subject No. 10 (M.P.). The fifth day was the earliest time period permitting a measurement of tissue strength and is an interval in which the peritoneal or inherent tissue differences of turgor thickness, and healing properties may cause variations in results. In addition, the normal momentum of healing is quite slow at this time, and difference in healing strength has not had time to develop. Thus it is that these 2 cases present quite similar numerical results and are important only as base lines for comparison and as starting points of the healing curve. The second interval is that of the seventh day and is represented in the deficiency group by subjects No. 4 (D.K.) and No. 5 (W.R.) and in the control group by subjects No. 11 (D.G.) and No. 12 (W.S.). When an average value of the rupture factors of each group is compared, it is found that there is a definite difference in favor of the control group (Fig. 19 and 20). If one considers that the groups are too small for averaging then the simple summation of these factors may be an adequate measure for comparison. Thus, the sum of the skin rupture factors for the two deficient subjects is 17.6 as compared with 31.7 for the controls. The sum of the fascium rupture factors for the deficient subjects is 10.6 as compared with 21.7 for the controls. Assuming the normal controls to represent a base line of 100 per cent, calculations reveal that in these deficient subjects the tensile

TABLE III

Diet	Subject N Initials	Tissue depletion* milligram ascorbic acid	Saturation test ascorbic acid		Rupture factor		% normal	
			Dose milligram	Secured level when in 5 hours milligram	Skin	Fascia	Skin	Fascia
C deficient	D K	20.4	954	4.23	6.03	97	80.9	30
C deficient	W K	37.3	96	1.80	66	8.54		
Normal control	D O	(None)	23.91	960.00		0	100%	100%
Normal control	W S	(None)	10.01	90	7.3	00		

*Tissue depletion. This is arbitrarily chosen as the total number of milligrams of ascorbic acid administered (including the saturation test dose) before blood plasma level of 1 mgm. per cc. was attained. The rate of administration following the first dose was usually 100 mgm. per day.

†The plasma ascorbic acid levels rose above 1 mgm. per cent upon administration of the saturation test dose of 5 mgm. ascorbic acid per kilogram of body weight 7; these deficit values in these control subjects.

‡For purpose of comparison, the control subjects are taken to represent 100 per cent of normal.

age proved to be less depleted than was suspected. This relative lack of depletion was reflected in a tensile strength higher than a corresponding deficient partner especially in the fascia, but was not up to the level of the control average. The amount of ascorbic acid spilled into the urine during this subject's saturation test was significantly more than that which was found in the other deficient subjects but yet it was not enough to be compared with any of the control subjects. Thus, it appears that while this subject was quite deficient, he still possessed a minimal amount of vitamin C in his tissues sufficient to obtain adequate healing (Table III).

The third interval is that which approximates the tenth day. The deficient group here consists of subjects No. 6 (L.M.) No. 7 (R.G.) and No. 8 (J.M.) two of these representing the ninth day of healing while the third represents the eleventh day. These can be compared with the ten day control subjects No. 13 (L.C.) and No. 14 (W.M.). The skin wound only was studied in subject No. 13 while only a fascial wound was studied in subject No. 14. The average of the rupture factors for the skin wound of the deficient subjects is 15.3 as compared with 53 for the control subject. The average of the rupture factors for the fascial wound of the deficient subjects is 10.5 as compared with 28.1 for the other control subject. Barring error due to use of a single control subject for skin and a single control subject for fascia (though both

were consistently comparable) and again assuming the normal controls to represent a base line of 100 per cent, it was found that in these deficient subjects the tensile strength of the suture line of the skin and of the fascia was reduced 71 per cent and 70 per cent, respectively. In other words the depleted subjects had by this time developed only 30 per cent as much wound holding power as was found in their corresponding normal controls. The tissue depletion studies and the saturation tests on these subjects revealed that enormous amounts of ascorbic acid were needed by the deficient group to attain a fast ing plasma level of 1 milligram per cent as compared with that required by the control subjects. These differences are quite evident even when the factor of inflammation in subjects No. 6 and No. 8 is taken into account. This correlation is shown in Table IV.

DISCUSSION

A review of the literature reveals only one instance of clinical scorbutic investigation related to the tensile strength determination of healing human wounds. In 1942 Bartlett, Jones and Ryan (4) studied the ascorbic acid content of small healing human thigh wounds of 6 supposedly healthy individuals with normal serum proteins who were convalescing from hernioplasties. By using the principle of a direct pull such as we have done, they also measured the tensile strength of the wounds. Five of the 6 subjects showed an adequate

TABLE IV

Diet	Subject No. initials	Tissue depletion*	Saturation test ascorbic acid		Rupture factor		% normal	
			Dose milligram	Secreted into urine in 5 hours milligrams	Skin	Fascia	Skin	Fascia
C deficient	J.M.	4200	H	H	8	6.3	70

Normal Control	E.W.	(none)	†	†		38		100

*Tissue depletion. This is arbitrarily chosen as the total number of milligrams of ascorbic acid administered, including the saturation test dose before a blood plasma level of 1 mgm. ascorbic acid per 100 ml. was attained. The rate of administration, following the test dose was usually 500 mgm. per day.

†I. Subjects marked "H" were hospitalized because of failure of biopsy wound to heal and could not come to laboratory for test.

†Proven normal control subject but no saturation test done at time of experiment.

holding power even though their vitamin C blood levels ranged as low as 0.20 milligram per cent. The sixth individual had a blood level of 0.09 per cent, a tissue ascorbic acid content of 0.0, and a tensile strength determination only one-fifth the average of the other 5 supposed normals. In this depleted subject, a second similar procedure was carried out on the opposite thigh (while the patient was convalescing from the second hernioplasty) an adequate amount of vitamin C then being administered for the next 10 days. The resulting specimen yielded a healing scar whose tensile strength was slightly above the group average while its ascorbic acid content was slightly below average. This isolated instance in the human subject was highly corroborative of the already known guinea pig experimentation correlating the strength of a healing wound with the ascorbic acid content of the tissues.

Our studies on the other hand have been on experimentally produced scorbutics, 9 in all, the other 5 subjects acting as controls. The results as shown graphically reveal the presence of a diminution in healing tensile strength which is more evident before the tenth day than after. In the case of the fascia, this difference approximates 50 per cent but after 11 days there is a development of parallelism such as to suggest development of satisfactory strength by the thirteenth or fourteenth day.

The same is true of the skin except that this difference approximates only 30 per cent diminution in strength through the first 8 days and because of the time lag in the deficient subjects, the percentage increases to 60 per cent during the tenth and eleventh days only to show the same tendency to parallelism nearing the thirteenth day. In other words early in wound healing it was noted that the fascia of the controls had the same wound strength on the seventh day as the deficient subjects on the eleventh while in the skin the comparable days were eighth and eleventh. In the later period the fascia of the controls achieved on the ninth day the same level of tensile strength as was found in the fascial wound of the deficient subjects on the twelfth day while in the skin the comparable days were tenth and thirteenth. The curves developed by Hartzell and Stone in guinea pigs (using a tensiometer principle for estimation of wound strength) reveal the same differences early in the course of healing, but their parallelism began around the eighth day and was such as to show a marked diminution in wound strength as late as the fourteenth day in the scorbutic animals. Their estimate was about one-quarter normal from the eighth through the fourteenth day, the latter being the termination point of their experiment.

In 1943 Jones Bartlett Ryan and Drum may reverted to guinea pig experiments and

found while working with ascorbic acid and sulfanilamide that certain of their results suggested that maximal saturation of the tissues with ascorbic acid aided in providing optimal tissue resistance to infection. Their lowest tensile strength determinations were obtained in animals with scurvy and wound infection. Their mortality figures were highly suggestive that more than a moderate tissue saturation was needed if ascorbic acid was to be of value in increasing tissue resistance. They concluded that complete saturation aided greatly in diminishing infection. This was interesting in the light of Hunt's fine work on the histological aspects of scorbutus. In 1941 he stated that not only is growth and migration of fibroblasts affected in healing wounds in vitamin C deficiency but phagocytosis is also inhibited."

With this in mind it is fitting to mention the complications encountered in the deficient subjects while convalescing from the biopsy surgery. As mentioned before the majority of the subjects underwent an elliptical excision of the suture line followed by a primary closure of the skin edges under a mild degree of tension. This could be considered as wound healing under slightly difficult circumstances. These subjects healed without complication according to the usual gross standards of external evidences of wound healing. Four subjects underwent an excision of the central portion of the wound; this excision being made at right angles in the form of an ellipse. This was followed by a primary closure of the wound. Such a maneuver resulted in a cruciate incision with a moderately severe degree of tension exerted on the healing surfaces. The necessary amount of undermining resulted in some diminution of blood supply to the apex of each skin flap. Circumstances as these could be construed as poor for healing under normal conditions. All four of the subjects chosen for this latter type of closure were from the deficient group. Three out of the 4 failed to heal by primary intention as evidenced by their accompanying photographs and case histories. All but a subject received ascorbic acid on the third day following biopsy during the performance of a saturation test followed by 500 milli-

grams of ascorbic acid daily until the plasma level attained 1 milligram per cent. The two exceptions were hospitalized because of wound infection appearing on the second day following biopsy at which time administration of ascorbic acid began. Massive doses of 1000 milligrams daily were administered in some cases after the plasma reached 1 milligram per cent when necrosis was severe, and continued until healing was complete. Final wound healing, therefore, occurred under the influence of administered ascorbic acid.

Subject No. 1 (D.A.) A white male aged 24 years, C deficient underwent his first skin and fascial incisions on October 17, 1943. The bleeding was so slight that no ligatures were needed in the subcutaneous tissues. Four sutures were placed in the fascia and seven in the skin. He returned to the hospital on the fourth postoperative day for his biopsy. The wound edges were fully intact and sealed throughout. There was no edema, no evidence of subcutaneous bleeding nor reaction around the sutures. The biopsy was carried out with the procedure which resulted in a cruciate closure. There was a moderate amount of tension on the transverse suture line. His subsequent course was marked on the fifth day following the biopsy by the appearance of a slight amount of skin necrosis in the point of each flap. Occasional sutures were removed and by the seventh day all sutures were out. By the ninth day the central necrosis had included an area 1.5 centimeters wide and 3.1 centimeters long (Fig. 7). The subject was now placed on large amounts of ascorbic acid for it was felt that the experimental phase of this process was now passed. Eventual secondary healing was completed on the forty-fifth day.

In regard to the biopsy tissue, both the skin and fascial specimens obtained presented excellent apposition of wound edges, but the slightest amount of handling resulted in dissolution at the suture line. The tensile strength of this tissue was too low to permit measurement, but adequate specimens were obtained for histological study.

Subject No. 6 (L.M.) A white male, aged 23 years, C deficient underwent his first skin and fascial incisions on October 17, 1943. There was minimal bleeding experienced so that no ligatures were needed. Four silk sutures were placed in the fascia and seven in the skin. Subsequent healing appeared to be satisfactory so that every other suture was removed on the fifth day and the remaining on the seventh day. There was a slight amount of redness about the sutures, but the wound was sealed. The edges were entirely intact, and there was no separation. There was no edema or sign of subcutaneous bleeding. The biopsy was performed on the ninth postoperative day at which time the wound appeared quite dry. The procedure used was the type that resulted in a cruciate skin closure. There

was slightly more tension in this instance than in subjects No. 1 and No. 8. The subject left the hospital 24 hours later but returned in another 24 hours with a temperature of 102.2 degrees F., a white count of 14,000 and a diffuse scarletina like rash over the trunk of the body. He had experienced chills and fever for the preceding 18 hours. It was recalled that he had a definite chill while on the operating table at the time of his recent biopsy. There was a small amount of serosanguineous drainage from the central portion of the wound, but very little, if any induration in the periphery. A few sutures were removed, a culture taken and hot wet dressings were applied. The throat cultures revealed a mixed growth of *Staphylococcus albus* and non-hemolytic streptococci while that from the wound showed a heavy growth of hemolytic *Staphylococcus albus*. The temperature peak was 100.8 degrees F on the following day and reached normal by the fifth day. The subject received a total of 200 cubic centimeters of scarlet fever convalescent serum during the first 2 days of the febrile course as well as an adequate amount of sulfadiazine. One of the clinicians believed that the subject presented a mild form of strawberry tongue and later while in the hospital, a slight scaling of his face and hands was noted. He was placed on a high ascorbic acid supplement to his diet, but wound healing was quite slow. The last sutures were removed on the seventh postoperative day. The central defect measured about 3 centimeters in diameter on the fourth day, but had increased to an area 5 centimeters wide and 6 centimeters long by the eleventh day (Fig. 8).

Subject No. 8 (J. M.) A white male aged 24 years, C deficient, underwent his first skin and fascial incisions on October 17, 1942. No ligatures were needed in the subcutaneous tissues. Four silk sutures were used for the fascia and seven for the skin. The progress of healing was satisfactory so that occasional sutures were removed on the fifth day and the remaining on the seventh. There was no evidence of inflammatory changes about the sutures. The biopsy was performed on the eleventh postoperative day at which time the wound edges were found to be excellently apposed, tightly sealed with no separation. There was no edema or sign of ecchymosis. The procedure used resulted in a cruciate closure with a moderate amount of tension on the transverse incision.

The subsequent course was unusual in that he developed a temperature of 102 degrees F. exactly 24 hours following the closure of the wound. This was also accompanied by some swelling and tenderness about the wound. His white blood cell count was 17,000. Because of the type of culture previously obtained from subject No. 6 it was deemed advisable to remove a few of the central sutures and apply heat to the wound. The temperature peak 24 hours later was 100.6 degrees F. reaching normal the following day. A culture from bloody fluid obtained from the wound at the height of the febrile reaction revealed the presence of a mixed growth of hemolytic strep-

tococcus. A few more sutures were removed on the fourth postoperative day which resulted in more separation of the wound in the transverse axis. At this time, there was no sign of any spreading infection. This subject was fed a diet with ascorbic acid supplement on the second day after the biopsy but his wound continued to break down so that the granulating surface measured 4 centimeters wide and 7 centimeters long on the ninth postoperative day (Fig. 9). The progress in healing was quite slow but gradually the granulations appeared healthy enough to accept a split thickness graft on the twenty-seventh day. He left the hospital 11 days later with the graft sufficiently healed to allow walking.

Subject No. 5 (IV. R.) A white male aged 25 years, C deficient, underwent his first skin and fascial incisions on October 17, 1942. No ligatures were needed in the subcutaneous tissue. Four silk sutures were placed in the fascia and 7 in the skin. Subsequent healing appeared to be satisfactory so that every other suture was removed on the fourth postoperative day. The biopsy was performed on the seventh day preceding which the remaining sutures were removed. The wound edges were found nicely approximated and well sealed with no separation. There was no edema but a slight amount of subcutaneous ecchymosis was noted. There was a slight redness about three of the last sutures removed. The skin biopsy was obtained by using the procedure which resulted in a cruciate closure. There was moderate amount of tension on this second suture line but the subsequent healing was very good. Every other suture was removed on the fifth postoperative day and the remaining on the seventh day. Photograph in Figure 6 was taken on the thirteenth day following the biopsy.

It is interesting to note that while all of these subjects came from the deficient group the lone subject who did heal primarily was not as deficient as the others. As a matter of fact, his response to the saturation test was intermediary between the control and deficient group (same subject previously given special mention under discussion of saturation test). Two of the three subjects who failed to heal primarily could be listed as complicated cases because of the obvious infection which developed but in the light of the above-mentioned work of Bartlett and his associates it would seem logical to assume that the end results of this poor wound healing and infection might be due to the deficiency status. If this is so it would seem that the vitamin C deficiency state exerts its greatest deterrent influence on tissue healing when circumstances for the latter are poorest i.e. in the more severe types of wound.

As early as 1923, Højer reported on the histology of experimental scurvy stating that the most constant change was an atrophy of the connective tissue fibers in all parts of the body. This study was confirmed by Wolbach and Howe in 1926 and climaxed in 1937 by Mazoué when the latter demonstrated the direct relationship of vitamin C to the production of collagen fibers. This relationship was confirmed by Querido and Gaillard in 1939 while in 1941 Hunt revealed that there might well be found many reticular fibers formed in scorbutic animals, but that these were low in collagen and thus suspected of being poor in strength. Such fibers have been referred to as precollagen fibers which do not mature without vitamin C. Hunt also noted that the proliferating mesodermal cells failed to mature under the same set of circumstances. Animal experimentation concomitant with this extended study further substantiated these microscopic observations and led to the conclusion that the absence of collagen or mature intercellular cement, results in a wound of poor holding power.

There is no doubt that the guinea pig presents a much more delicate mechanism for presenting the picture of experimental scurvy. It develops severe scurvy in 2 to 3 weeks, whereas many months are necessary to elicit a similar response in man. In the guinea pig there even is a gross difference in the appearance of scorbutic wounds due to the presence of edema along the suture lines with some evidence of mild inflammation plus heavy bloody crusts as late as the eighth and tenth postoperative days. As late as the fourteenth day these wounds are hard and thick as compared to those in the normal guinea pig. Under such circumstances, it is not difficult to diagnose the presence of scurvy with or without the microscope the essential findings being the edema, pools of unorganized bloody exudate the presence of some reticular fibers, and the absence of collagen. In the human subjects our findings in most instances are entirely the same save for the frank edema, but while the deficiency can be noted in the histological section in some instances it has been difficult to estimate the tensile strength of a particular wound from its microscopic

appearance. This is particularly true if the healing time is not considered in evaluating the lack of intercellular cement. Thus, if a suture line presents a total absence of collagen after 10 days of healing one might forecast a marked diminution in tensile strength, but a comparable situation would not be present after 5 days of healing since the holding power at that time is not so dependent upon the same mechanism. This difficulty is more pronounced where only partial microscopic evidence of the deficiency exists. The explanation for this may vary all the way from the technical difficulties of a two dimensional tissue study to the specificity of ascorbic acid utilization on the part of the individual. Since the completion of our study this matter has been brought up by Bourne who found that 'wounds in scorbutic animals which are receiving different doses of vitamin C may be very similar in general histological appearance but may have very different tensile strength. Despite this relatively minor problem, the overall microscopic picture in this series is entirely in keeping with the findings of other investigators. The slides, for example of subject No. 8 (J. M.) are outstanding in the series of deficient subjects, showing almost no collagen or reticulum in the fascia (Fig. 10) and a minimal amount next to the epithelium in the skin (Fig. 12) 11 days after the initial incision was made. Fibrocytes were fairly plentiful at the borders of the incision but none was seen in the central portion of the wound which was filled with a fibrin clot.

CONCLUSIONS

1. Human subjects on prolonged ascorbic acid depletion exhibit an approximate 50 per cent diminution in tensile strength of healing wounds.
2. Such depletion delays the development of tensile strength in an uncomplicated healing wound from 3 to 5 days up to the fourteenth postoperative day.
3. When circumstances for healing are poor such as the presence of undue wound tension or diminution in blood supply this depletion in ascorbic acid is made more evident through gross failure of primary wound healing.

4 The incidence of wound infection under such circumstances suggests the need for ascorbic acid in the tissues for maximum resistance to infection by favoring primary wound healing

5 Human subjects on prolonged ascorbic acid depletion exhibit a recognizable lack of collagen and reticulum in their healing wounds.

THE EXCRETION AND CONCENTRATION OF PENICILLIN AND STREPTOMYCIN IN THE ABNORMAL HUMAN BILIARY TRACT I GALL BLADDER

JERRY ZASLOW M.D. VIRGIL S. COUNSELLER, M.D. F.A.C.S. and
FORDYCE R. HEILMAN M.D. Rochester Minnesota

IN recent years penicillin and streptomycin have been subjected to rather extensive clinical and experimental investigation. The excretion of these substances into the normal biliary tract of man has been reported in a few papers (4, 8, 14). Although hope that the antibiotics may prove useful in diseases of the biliary tract has often been expressed, no one has reported any studies on the excretion and concentration of these substances in the abnormal biliary tract of human beings. The present study was undertaken with the specific purpose of determining the rôle that these antibiotics might play in diseases of gall bladders and bile ducts of human beings.

While it must be admitted that it is easier to control observations on the lower animals than on man, it was decided in this study to approach the problem directly by observations on human beings for even after animal experiments are concluded the actual status of the matter in man is still in question. Differences in physiologic processes, both normal and abnormal, in different species of animals are known to exist. Although definite limitations were encountered in an investigation of the type conducted here, the results have given some definite impressions as to the use of penicillin and streptomycin.

REVIEW OF THE LITERATURE

Penicillin in bile In 1941 Abraham and his associates first reported that penicillin was excreted in the bile of rabbits. It was not until 1943, however, that Rammelkamp and

Helm studied excretion of penicillin in bile in man. By introducing a nasal tube into the duodenum of each of 5 normal persons and removing specimens every 15 minutes after intravenous injection of 20,000 units of penicillin, they found that penicillin was present in bile from both the liver and gall bladder. They were able to demonstrate penicillin in bile as early as 15 minutes after injection and it was present for as long as 2 hours. In 1 case, after a single intravenous injection of 20,000 units, levels in the blood and in bile removed from the common duct by means of an indwelling T tube were determined. They observed, first that the concentration in the bile exceeded that in the blood, indicating that the liver concentrated the drug; second, whereas no penicillin was demonstrated in the blood after 2 hours, it was still present in hepatic bile up to 2½ hours. Struble and Bellows, while investigating the distribution of penicillin in the eye of the dog after a single massive dose, also noted that the drug was present in bile in high concentration for a long period.

Streptomycin in bile The reports concerning the activity of streptomycin in bile are limited to 3. Stebbins, Graessle, and Robinson (10) reported that rabbits excreted 8 to 10 per cent of the drug in the bile after 5,000 units per kilogram of weight had been given intravenously. Following a single intravenous injection of 600,000 units in 2 patients, Zintel and his associates found the maximal concentration in bile was attained in 2 hours. In 1 case the level reached 7.5 units per cubic centimeter and in the other 3 units per cubic centimeter. In each case the concentration in the blood reached more than 30 units per cubic centimeter in 15 minutes, and fell to 18 units in 2 hours. It was interesting to see a lag

Abridgment of portion of thesis submitted by Dr. Zaslow to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of M.S. in surgery.

From the Division of Surgery, Mayo Foundation and the Divisions of Surgery and Bacteriology, Mayo Clinic.

in the appearance of streptomycin in the bile of 1 patient. No activity was present for the first 30 minutes, even though the level in the blood was high at that time. In addition, in neither case did the concentration in the bile exceed that in the blood. Heilman and her associates (4) found 125 units per cubic centimeter of the bile and 6 units per cubic centimeter of blood 2 hours after a single subcutaneous injection of 100,000 units of streptomycin indicating that streptomycin was concentrated in the bile of human beings. When 100,000 units were given subcutaneously every 3 hours for several days, the concentration in the bile on the second and third days was between 3 and 6 units per cubic centimeter.

STUDY OF PENICILLIN AND STREPTOMYCIN IN BILE FROM THE GALL BLADDER

Method. Twenty five patients who were to undergo cholecystectomy were selected for the study of each antibiotic agent. At periods varying from 12 minutes to 14 hours before operation, each patient was given a single intramuscular injection of either 15,000 units of penicillin or 100,000 units of streptomycin, doses commonly used clinically. No food was given to the patient after the antibiotic agent was administered. The time interval between injection of the antibiotic agent and clamping of the cystic duct at operation was noted. The levels of penicillin or streptomycin in the bile obtained from the gall bladders of these patients were determined in all cases. The level of penicillin was determined by Fleming's modification of the Wright slide cell technique as described by Heilman and Herrell (5). The organism used for the test was a strain of hemolytic streptococcus. The level of streptomycin was determined by a method similar to the cup-plate method of assay employed by Stebbins and Robinson (11). The organism was a sensitive strain of *Staphylococcus aureus*. The test plates were placed in the icebox for 20 hours to allow the streptomycin to diffuse from cups then in an incubator overnight, and the zones of inhibition were read.

A note was made of the report by the roentgenologist of the function of the gall bladder

and of the presence and position of stones in the gall bladder and of the condition of the liver and its excretory apparatus at operation.

Results. Penicillin.—In the 25 cases in which penicillin was used three conditions were noted: nonfunctioning gall bladders with stones, functioning gall bladders with stones and gall bladders without stones. The motor activity of the gall bladder had been determined by the roentgenologist by means of the Graham-Cole test. In the 3 cases in which cholecystectomy was performed and no stones were found, the roentgenogram showed nonfunctioning gall bladders in 2 cases and a functioning gall bladder with stones in the other case.

The results of this study are given in Table I. No penicillin was found in the bile from 5 of the 10 nonfunctioning gall bladders with stones. The time intervals after injection of penicillin in these 5 cases varied from 12 minutes to 12 hours. In these 5 cases a stone was found impacted in the cystic duct at the time of operation and the gall bladders in 4 of these were reported by the pathologist to be hydropic. The levels of penicillin in the other 5 cases in this group varied from 0.25 unit to 1 unit per cubic centimeter. The cystic ducts in these cases were patent.

In only 3 of the 12 cases of functioning gall bladder with stones was no penicillin recovered. In 2 of these the cystic duct was found to be obstructed at operation. In 1 case the duct was patent, but subsequent study showed that penicillin was not excreted into the hepatic bile in this case. In all of the other 9 cases in this group the cystic duct was patent, the levels varied from 0.06 to 1.9 units per cubic centimeter, and the time intervals after injection of penicillin varied from 45 minutes to 14 hours.

In 3 gall bladders no stones were found. In these the levels of penicillin were 0.24 unit, 1.0 unit and 0.12 unit per cubic centimeter of bile at 45 minutes, 1 hour and 15 minutes and 10 hours and 45 minutes after injection of penicillin respectively.

In the entire group in cases in which levels were obtained at long intervals after injection (9 to 14 hours) penicillin was still present in all those in which the cystic duct was patent.

varying from 0.06 to 1.0 unit per cubic centimeter

Comment.—Analysis of these results reveals several important facts. In any case in which the cystic duct was obstructed by a stone no penicillin was demonstrated in the contents of the gall bladder. When the cystic duct was patent, penicillin was usually found in rather high concentration. When these results are compared with those obtained from a subsequent study of excretion of penicillin in hepatic bile (13) it is obvious that in general the level of penicillin in bile of gall bladders removed soon after parenteral administration

is equal to or slightly lower than the highest level which might be expected in the hepatic bile up to that time and is either equal to or somewhat higher than that in the blood. In those cases in which many hours elapsed between administration of penicillin and cholecystectomy the levels obtained indicated that neither marked concentration, rapid absorption nor ejection of the antibiotic agent from the gall bladder had occurred. In no such case did the level of penicillin exceed 2 units per cubic centimeter. This was true even in cases in which concentration function was excellent as shown by the Graham-Cole test.

In addition, the darkness of the bile, an index of the ability of the gall bladder to concentrate, did not seem to affect the level of penicillin.

Streptomycin—Results are given in Table II. There were 10 nonfunctioning gall bladders with stones. Of these, no streptomycin was found in the bile from the gall bladder in 6 cases. In 5 of the 6, the cystic ducts were obstructed completely, and 1 of the 5 gall bladders contained thick creamy pus. In the sixth case, although the cystic duct was patent, no streptomycin was found in the contents of the gall bladder after 12 hours. This patient had active obstructive jaundice with high levels of serum bilirubin, and it is likely that no antibiotic agent was excreted from the liver (this phenomenon is described more fully in a subsequent report, 13). Streptomycin was recovered from the gall bladders in 4 cases, the levels varying from 1.5 to 2 units per cubic centimeter. The time intervals after injection were from 1 hour to 12 hours. The cystic ducts in these 4 cases were patent.

In the 14 cases of functioning gall bladders with stones, no streptomycin activity was found in 5. However, the time intervals after injection in 3 were less than 1 hour, and subsequent study showed that there often was a lag of a half hour or more in the appearance of streptomycin in hepatic bile (13). In the other 2 cases in which no streptomycin was found in the bile from the gall bladder, the cystic duct was obstructed, and in 1 of these the gall bladder was hydropic. In the remaining 9 cases the level of streptomycin varied from 0.8 to 3.9 units per cubic centimeter of bile and the time intervals after injection varied from 1 hour to 12 hours. The cystic ducts in these 9 cases were patent.

One gall bladder contained no stones. However, no streptomycin was demonstrated 2 hours and 10 minutes after injection. Further study revealed that this patient had marked impairment of hepatic function, as shown by the hippuric acid excretion test, and also an elevated level of serum bilirubin.

In all cases of gall bladders in which levels were obtained after long intervals (10 to 12 hours) streptomycin was still present in all those in which the cystic duct was patent,

the highest level being 1.5 units, the lowest, 0.98 unit per cubic centimeter of bile.

Analysis of these results leads to the same conclusions as were reached when penicillin was used.

COMMENT

Any substance given parenterally may reach the lumen of the gall bladder by one of two routes either through the bile or by way of the blood vessels in the wall of the gall bladder. It is known that the gall bladder fills passively when the pressure in the common duct reaches a critical level of 50 to 70 millimeters of water. Therefore, if the antibiotic agent reaches the bile in the gall bladder through the biliary tree, when the cystic duct is patent the level of the antibiotic agent obtained in the bile of the gall bladder should be either equal to the highest level in the hepatic bile up to that time or somewhat lower than this highest level as a result of dilution in the gall bladder which may already have contained bile before the excretion of antibiotic agent from the liver started.

If on the other hand the agent does not reach the lumen of the gall bladder through the biliary tree, it may be supposed that it does so through vessels in the wall of the gall bladder. That this does not occur is proved by the results of the present study.

From this investigation it appears that the major factor concerned in the presence of penicillin or streptomycin in the bile of the gall bladder is the patency of the cystic duct. Lynn and his co-workers came to a similar conclusion while studying excretion of sulfonamides in dogs in which the cystic ducts were experimentally obstructed. In all of the cases in the present study in which the duct was obstructed completely by a stone, the antibiotic agent was not recovered from the contents of the gall bladder.

This is a significant observation since in most cases of acute cholecystitis and empyema obstruction of the cystic duct is also present (2, 3, 6, 9). When these conditions coexist penicillin or streptomycin is almost certain not to get into the lumen of the infected gall bladder. Although antibiotic agents do reach the tissues of the gall bladder through the

blood stream, and conceivably may help control infection in the wall, it is unlikely that these agents will overcome the infection present in the bile in the lumen. While it is true that, in the main, the cases in this study were examples of chronic disease of the gall bladder the fact that in 4 cases reported by the pathologist to be acute cholecystitis superimposed on chronic cholecystitis the antibiotic agent was not found in the bile at least suggests that acute inflammation does not alter the mode of entrance.

In chronic cholecystitis with stones, the effectiveness of penicillin or streptomycin in sterilization of the contents of the gall bladder in any given case cannot be predetermined, because in only some of the cases of this type does the drug reach the bile of the gall bladder. The cystic duct of a gall bladder with stones may become obstructed at any time. However once the antibiotic agent has entered the lumen it remains there for many hours in fairly high concentration, since it is neither rapidly absorbed nor ejected from the gall bladder.

SUMMARY AND CONCLUSIONS

After intramuscular injection of 15,000 units of penicillin or 100,000 units of streptomycin, no antibiotic agent was found in the bile of gall bladders in cases in which the cystic duct was obstructed. Antibiotic agent was found in large amounts in gall bladders in which the cystic duct was patent, provided that the antibiotic agent was excreted normally from the liver.

The roentgenologic report was of little value in indicating from which gall bladders the antibiotic agent would be recovered.

The antibiotic agent was neither highly concentrated nor rapidly absorbed nor ejected from the lumen of the gall bladder.

Penicillin and streptomycin may prove of no value in acute obstructive cholecystitis.

The usefulness of penicillin or streptomycin in any given case of chronic cholecystitis with stones is uncertain.

TOTAL GASTRECTOMY FOR CARCINOMA OF THE STOMACH

WILLIAM P. LONGMIRE, Jr. M.D. Baltimore, Maryland

IN the period from July 1, 1944, to December 1, 1945, a series of 25 patients with carcinoma of the stomach were operated upon. In 20 of these cases, total gastrectomy was performed with 2 immediate deaths and an operative mortality rate of 10 per cent.¹ Seven patients have now survived for over a year, have resumed a part of their previous occupations, and with a special dietary and medical regimen show little clinical evidence of digestive or metabolic disturbance.

In the present series all the neoplasms were at least moderately extensive, and some had invaded the entire stomach. These results, however, together with the recent successful reports of Horsley, Farris, Ransom, and Collier, Jones and Kehm, and others have led to the belief that the operability rate and the percentage of 5 year cures following the surgical treatment of malignant gastric neoplasms would be increased if total gastrectomy were more frequently employed even in the treatment of the smaller early lesions of the pylorus and fundus. All of the neoplasms encountered in the present series originated in the pyloric or fundic portion of the stomach. Tumors of the cardia, although sometimes successfully treated by total gastrectomy, have characteristic metastatic pathways which present special surgical problems. Treatment of lesions of the cardia of the stomach is not included in the present discussion.

DISCUSSION

The careful study of the regional lymphatic metastases of carcinoma of the stomach made

by Collier, Kay and MacIntyre lends strong support to the more frequent use of total gastrectomy. These authors found it impossible to tell without microscopic section whether lymph nodes were invaded by metastases unless they were definitely replaced by carcinoma. There were metastases to regional lymph nodes in 75.5 per cent of the cases they studied. The upper margin of the neoplasm in the wall of the stomach could not be determined by palpation alone at the time of operation in 24.5 per cent of the cases. There was no relation between the duration of symptoms or the size of the neoplasm and lymphatic metastasis. The authors conclude that whether palpable lymph nodes are or are not present, the regional lymph nodes should be included within the resection to increase the likelihood of cure.

The chances of complete eradication of a malignant tumor would certainly be greater with block excision of the entire stomach and regional lymph nodes than with local excision of the growth or subtotal resection of the stomach. Just as radical mastectomy and abdominoperineal resection of the rectum are preferred in the treatment of malignant lesions of the breast and the rectum respectively, so total gastrectomy I believe should be the procedure of choice in many cases of malignant gastric tumor which at the present time are routinely treated by subtotal resection. The more widespread use of such a procedure is dependent upon the development of a technique which lowers the operative mortality and postoperative complications to compare more favorably with those of other types of gastric resection, and upon evidence that the human body can adapt itself to the absence of a stomach and maintain a satisfactory nutritional state.

Reports from various clinics indicate that the operative mortality following total gastrectomy is declining. Jones and Kehm have

¹From the Department of Surgery of the Johns Hopkins Medical School and the Johns Hopkins Hospital.

²One other successful total gastrectomy not included in this series was performed on a patient with a large benign gastric ulcer. At operation the lesion was thought to be a neoplasm. Since that time the diagnosis of malignancy has been established by routine microscopic section before continuing the operation. Thus the operative mortality for all 26 total gastrectomies is just under 10 per cent.

recently reported 8 consecutive cases without a death. Farris, Ransom, and Collier in 1943 had only 2 deaths in 19 cases, one of a patient 79 years old. In 1943 Horsley reported 3 total gastrectomies without a death. These series, although small, indicate that the mortality rate of total gastrectomy is being lowered to compare more favorably with that following other types of gastric resection for malignancy.

As regards the adaptation of the gastrointestinal system to the absence of a stomach over a period of years our knowledge is limited for in the past, total gastrectomy has been reserved for such advanced malignant disease that most of the patients have died within a few months. In all, 16 patients (10) are known to have survived for over 3 years, and all of these patients were able to lead an active life with few dietary restrictions. Farris, Ransom and Collier studied the digestive function of 4 patients who had survived total gastrectomy for over 4 years. They found no evidence of disturbance in the digestion of fats and proteins. The absorption of glucose was more rapid than normal. The chief disturbance noted was in the metabolism of iron. In the absence of hydrochloric acid from the stomach the ferric and organic iron in the diet were not absorbed and hypochromic microcytic anemia developed unless the patients were given ferrous iron regularly. On the other hand, Rekers, Pack and Rhoads found in 3 patients 6 months after the performance of total gastrectomy impaired ability to digest or absorb the fat of the diet and 1 patient had impaired ability to digest or absorb the protein of the diet. Their patients had normochromic normocytic anemia. According to Pack and McNeer of 80 patients who have survived total gastrectomy 82.5 per cent subsequently died of metastasis. In the remainder of the group there were 4 cases which suggested that the interference with nutrition following total gastrectomy had been severe enough to cause death. Two of these patients died of anemia, 1 of general weakness and 1 of acute enteritis.

In summarizing this point there are three important considerations (1) Sixteen patients are known to have led a fairly normal

life for more than 3 years after total gastrectomy. (2) A few patients have apparently been unable to adjust the digestive apparatus to the absence of a stomach and in some instances death has ensued as a direct result. It is possible that these patients might have survived if more detailed and prolonged post-operative care had been instituted. (3) The majority of the patients have died of metastasis before follow up studies could be made. The final answer must await further clinical experience and study. The present series gives some additional information regarding this phase of the problem.

CASE MATERIAL

All of the patients in this series were seen in consultation with Dr. Alfred Blalock, Professor of Surgery and Director of the Department of Surgery in the Johns Hopkins Hospital. In using the term "total gastrectomy" the criterion of Finney and Rienhoff has been followed, that is, removal of the entire stomach including the pyloric and cardiac sphincters.

In this series there were 15 male patients and 5 female patients. The ages ranged from 37 to 76 years, all but 4 were over 55. Although in some instances it was very difficult to tell exactly when the symptoms due to the carcinoma began, the duration of symptoms ranged from 13½ months to 111 months. Four patients had had similar symptoms for many years which had been attributed to peptic ulcer. In 2 patients a scarred duodenal ulcer was found in addition to the gastric carcinoma. In 2 instances it was definitely established that the neoplasm originated in a large chronic gastric ulcer. With the exception of one whose weight had remained unchanged, all of the patients had lost from 15 to 20 pounds in weight.

On admission to the hospital the hemoglobin content of the blood of these patients ranged from 5.0 to 15.6 grams, with an average value of 11 grams. In 14 patients determinations of the blood chemistry were made. The total serum protein was below normal in only 2 patients. There was a slight decrease in the blood chlorides in 4 patients. Seven patients had 0.0 free acid in a fasting specimen

of gastric juice, in the others the free acidity ranged from 8 to 48 degrees. Roentgen and fluoroscopic examinations were made of the stomach after the ingestion of barium in 16 patients. The presence of a neoplasm was correctly diagnosed in all but 1. In this patient the presence of an ulcerative lesion was noted in the report, but it was not stated that this was due to neoplasm. The changes in the contour of the stomach noted upon roentgen examination agreed closely with the extent of the gross lesion of the stomach found at operation.

As regards the general medical condition of the patients before operation, it was found that 1 patient had rheumatic heart disease with mitral and aortic insufficiency, hypertension and cardiac hypertrophy. Six other patients had advanced arteriosclerosis, one with a history of angina pectoris and another with hypertension. The serologic test for syphilis was positive in 4 patients although there were no clinical signs of the disease. One

patient had an extensive fibroid infiltration throughout both lungs which was thought to be due to inactive tuberculosis. One patient had mild diabetes mellitus with a blood sugar determination of 131 milligrams per cent.

The following classification groups the cases according to the approximate portion of the stomach wall invaded by the tumor (Table I). The entire stomach wall was invaded in 3 instances. In 5 patients the growth extended throughout the length of the lesser curvature. The distal half of the stomach wall was infiltrated in 5 patients and the distal one-third in 2. The lesion was restricted to the pyloric antrum in 4 instances. One patient had a large chronic gastric ulcer with malignant changes about the periphery. Three patients showed no evidence of extension to the regional lymph nodes. There was 1 patient with involvement of the lymph nodes of the lesser curvature, 1 with involvement of the lymph nodes of the greater curvature, and 1 with involvement of the lymph

Fig. 1. G.B. Operative specimen. Entire stomach, omentum, spleen, and distal three-fourths of pancreas.

nodes along both curvatures. In 9 patients there was extension to the lymph nodes about the pylorus along the lesser curvature and about the left gastric artery. Lymph nodes about the pylorus, along both curvatures, and about the left gastric artery were invaded in 5 cases.

The spleen was removed with the stomach in 7 patients. In 4 patients there was direct extension of the growth into the body of the pancreas and in 2 of these patients it was necessary to remove three-fourths of the pancreas and the spleen together with the stomach¹ (Fig. 1). A portion of the peritoneum overlying the middle colic vessels in the transverse mesocolon was removed in one case in which there was direct extension of the carcinoma into this area. The growth had extended into the duodenum in 3 patients and into the esophagus in one.

During this same period an exploratory operation was performed upon 5 other patients who had carcinoma of the stomach with generalized carcinomatosis. In 2 a posterior

gastroenterostomy was performed. Thus of 25 patients with carcinoma of the stomach operated upon during this period, total gastrectomy was performed in 20 or 80 per cent.

OPERATIVE TECHNIQUE

The operative technique is as follows. The abdomen is entered through an upper midline incision which extends from the apex of the left xiphocostal notch to the umbilicus. A specimen for examination by frozen section is taken of the original lesion or of a grossly involved regional lymph node. The extent of the lesion is determined. The liver the cul-de-sac, and the regional, mesenteric, and aortic lymph nodes are palpated. If resection is decided upon the omentum is freed from the transverse colon and removed with the stomach. The right gastric and gastroepiploic arteries are divided as close to their origins as possible and the duodenum is freed down to the head of the pancreas and divided. The stomach is freed posteriorly. If there is evidence of peritoneal implants or extension of the tumor the peritoneum of the posterior wall of the lesser peritoneal sac is removed. When difficulty is encountered in visualizing the vasa brevia, the spleen is mobilized laterally by freeing its peritoneal attachments. If bleeding is troublesome in this region or if extension to the splenic lymph nodes is suspected the main splenic vessels are divided and the spleen is removed with the stomach. With the greater curvature mobilized, the stomach is reflected upward and to the left a maneuver which brings the left gastric vessels clearly into view. The left gastric vein is traced down to the splenic vein and divided. The left gastric artery is ligated at the celiac axis and all lymph nodes in the region are removed.

At this point a peritoneal flap is raised which starts from the gastrohepatic omentum and extends across the esophagogastric junction to the left side of the diaphragm. This flap is elevated and the vagus nerve on each side of the esophagus is divided. This procedure allows the abdominal esophagus to stretch and the cardia of the stomach to drop down several centimeters. Only enough of the areolar tissue is divided to allow clear

¹In one of these patients surgical diabetes developed after operation, the blood sugar rising to 400 milligrams per cent on the 15th postoperative day. At that time 3 units of precurdine zinc insulin daily were required for regulation. During the next week the blood sugar slowly declined to normal and remained so. At the time of discharge on the 31st postoperative day there was no sugar in the urine. The blood sugar was 100 milligrams per cent, and the patient was taking 10 units of precurdine zinc insulin daily. Although the extent of the pancreatic excision was the same in the second patient, the disturbances of his blood sugar were normal throughout his postoperative course.

Fig. 2 a. Stomach freed and retracted over upper angle of incision. Posterior row of interrupted silk sutures placed between jejunal loop and posterior wall of esophagus. b. Opening made into lumen of esophagus and jejunum. Second posterior row consists of interrupted catgut sutures which pass through the entire thickness of the wall of esophagus and jejunum.

identification of the wall of the esophagus. No attempt is made to free the esophagus up through the diaphragm.

Both an antecolic and a retrocolic esophagojejunostomy have been performed now, however the retrocolic type is generally employed. The chief advantage of this type is that at times the jejunal mesentery is short and difficulty is encountered in getting the jejunum up to the esophagus. Placing of the jejunum anterior to the colon causes further shortening of the mesentery. When the retrocolic method is followed the transverse mesocolon is sutured across the intestine obliquely as recommended by Morton. In 3 of the cases in this series it has been necessary to divide one of the primary mesenteric arteries to the jejunal loop to afford sufficient length for the anastomosis. One row of interrupted silk sutures is placed between the posterior wall of the esophagus and the jejunum and the sutures are tied (Fig. 2a). The posterior wall of the esophagus is divided and a correspond-

Fig. 3 Esophagojejunal anastomosis completed. Peritoneal flap sutured to jejunum. Transverse mesocolon sutured obliquely across jejunal loop.

ing opening is made in the jejunum. The second row of sutures is formed of interrupted catgut sutures which pass through the entire wall of the esophagus and jejunum and carefully approximate the mucosal edges (Fig. 2b). The anterior wall of the esophagus is divided and the two rows of sutures unite the anterior edges in similar fashion. The peritoneal flap previously formed is now sutured over the anastomosis to the jejunum (Fig. 3). This step helps to support the suture line as well as to reinforce the suture line.

The procedure as outlined is a combination of certain features of several different methods of certain features of several different methods previously described by others. There are however points which should be emphasized as being particularly important. In an attempt to reduce the magnitude of the operation all of the steps that are not essential have been eliminated. Enteroenterostomy recommended by most operators, is usually unnecessary and has not been used. An enterostomy for feeding the patient after operation is unnecessary if the patient is properly prepared before operation and modern intravenous therapy is used after operation. Numerous other steps such as duodenojejunostomy and complicated esophagojejunal anastomoses have been omitted. A simple upper midline incision gives ample exposure and is quickly opened and closed with mini-

mal loss of blood. The duodenum should be divided as close to the head of the pancreas as possible. This permits complete removal of all pyloric lymph nodes and is an additional safeguard in those cases in which there is extension of the gastric carcinoma into the duodenum. Three such cases were encountered in the present series.

With the stomach well mobilized and elevated out of the wound, the left gastric vessels are clearly visualized. They are divided at the celiac axis and all surrounding lymph nodes removed. As this region is a pathway of early dissemination by the lymph nodes, this step is important. The esophagus is mobilized and exposed just enough so that its walls are clearly defined. Every effort is made to preserve its blood supply. The diaphragmatic and mediastinal esophagus are not disturbed unless extension of the growth into the abdominal esophagus necessitates this step. The abdominal esophagus is surrounded by fibrous areolar tissue which if left intact holds sutures better than the bare muscle of the mediastinal esophagus.

There have been no signs of structure formation at the site of anastomosis in any of these cases. The use of interrupted sutures through out the anastomosis is important in preventing this complication. Great care is used in placing all of these sutures although this care is tedious at times, the rewards are great. Forty per cent of the reported operative deaths following total gastrectomy have been due to leakage from the line of anastomosis (10).

POSTOPERATIVE COURSE

In this series of 20 cases there were 2 immediate deaths. In 1 patient who died an attempt was made to form a food reservoir from the loop of jejunum that was anastomosed to the esophagus. The blood supply of a portion of the jejunum adjacent to the esophagus was impaired by the procedure. Gangrene developed in this area with perforation on the 10th postoperative day and the patient died of generalized peritonitis.¹ The second operative death occurred in a 43 year old colored female who had a mild diabetes mellitus.

Total gastrectomy was performed on October 23, 1943, for an extensive carcinoma which involved the distal third of the stomach with metastasis to the regional lymph nodes. Twenty four hours after operation the patient's temperature rose to 103 degrees and signs of pneumonia appeared in the left lung. In spite of the administration of penicillin and sulfamerazine her condition grew steadily worse. Forty-eight hours after operation pulmonary edema developed and she died a short time later. Of the other immediate complications only one has been serious. In this patient acute pancreatitis developed on the second postoperative day which slowly subsided with conservative treatment, however as soon as oral feedings were started he showed signs of partial high intestinal obstruction and a second exploration was performed on the 18th postoperative day. It was found that a loop of upper jejunum was bound to the lateral peritoneal wall by adhesions in the left upper quadrant, causing intestinal obstruction. The adhesions were released. The remainder of the patient's postoperative course was uneventful. In 2 patients venous thrombosis developed in a lower extremity which was treated by ligation of the femoral vein. There was 1 case of postoperative atelectasis which responded quickly to intratracheal aspiration and the administration of penicillin. There have been no difficulties with the line of anastomosis there have been no fistulas, intra abdominal abscesses or strictures. The average postoperative stay in the hospital for these patients has been 25 days.

The adjustment of the alimentary tract to the absence of the stomach has been remarkable. The patients have been given water in small amounts by mouth on the 4th postoperative day. The amount has been increased gradually and other liquids have been added. By the 10th postoperative day almost all of the patients have been able to take a soft diet divided into 6 small feedings. After starting to eat solid food 5 of the patients complained of heartburn and 9 of a feeling of abdominal fullness after eating. The heartburn responded quickly to small doses of amphogel. The feeling of fullness was more troublesome. This symptom has been at

¹Two cases in which this method was successfully used were later reported by Engel.

tributed to the limited capacity of the jejunum, and the patients were given frequent small feedings. In some of these patients this discomfort has continued for months after operation. Two patients have had transient diarrhea during the second postoperative week which subsided spontaneously. One to 3 soft formed stools a day is the usual bowel habit for these patients.

Roentgenograms taken at the time of discharge showed 2 instances in which there was slight delay in the passage of barium from the esophagus into the jejunum. Both of these patients were asymptomatic, however. In another patient the barium passed into the proximal loop which was dilated. In none of the patients was there any retention of the barium in the proximal loop after 5 hours. De Amesti has reported an instance of great dilatation and retention in the proximal loop in a patient without an enteroenterostomy between the afferent and efferent loops and he stresses the importance of performing such an anastomosis. It is my opinion however that if the esophagojejunal anastomosis heals without undue scarring or stricture formation there is no delay in the emptying of the proximal loop. Four of these patients have complained of occasional regurgitation of small amounts of bile stained fluid as long as 2 months after operation. Thus far however this regurgitation has not been sufficiently frequent or severe to warrant the performance of an enteroenterostomy as a routine part of the operative procedure. The barium passed through the small intestine more slowly than normal in 2 patients, and in another there was delay in the ileum suggestive of partial obstruction. This patient's progress while in the hospital was rather slow and he vomited small amounts on a number of occasions. Since discharge however he has improved. He has gained weight and has returned to work.

With the exception of a slight decrease in blood chlorides in 6 patients, all blood chemistry values were within normal limits at the time of discharge. These included nonprotein nitrogen, carbon dioxide combining power, chlorides, total proteins, albumin and globulin. The hemoglobin content of the blood at the time of discharge ranged from 10.8 to 14.9

TABLE II.—CAUSE OF DEATH

Name	Survival period	Cause of death
E.W.	2 weeks	Slough site of gastric pouch
A.H.	2 days	Pneumonia cardiac failure

F.B.	3 months	Insanition
G.P.	2½ months	Recurrence

grams with an average of 12.4 grams for the group.

FOLLOW UP STUDIES

Tables II and III summarize the condition of these patients at the time of this report. It has been 1 year and 7 months since the first operation. The last gastrectomy in this series was performed 4 months ago. Ten of the patients who were submitted to total gastrectomy have died. In addition to the 2 operative deaths described, 6 patients have died of recurrence of the carcinoma. It is not surprising if we bear in mind the extent of their lesions, that 5 of the patients have died of recurrence within 3 months after operation. On the other hand, some of the patients with the longest survival periods have had even greater involvement of both stomach and regional lymph nodes than those who have died so soon of recurrence.

In this limited series with the relatively short time that has elapsed since operation, no correlation can be made between the size and type of the lesion or of the regional lymph node invasion and the survival time. In none of the cases was total resection attempted if distant metastasis was thought to be present at the time of operation. Two of the patients with rapid recurrence of the carcinoma showed extensive metastatic implants over the visceral and parietal peritoneum at the time of death and it might be suspected that operative trauma was directly responsible for this extensive 'seeding' of the peritoneal cavity. In 2 other patients with recurrence

TABLE III.—PRESENT CONDITION OF SURVIVORS

Name	Postoperative interval	Weight	Appetite	Food capacity	Gastrointestinal symptoms	Stools	Work
J.W.	10 months	Outlying slowly to the under best weight	Good	Meets eat small meals	Occasional burning and fullness after meals	Normal r.i.d.	Regular

one of whom survived 7½ months, large retroperitoneal masses developed along the aorta suggesting that the malignant condition had spread to unsuspected lymph nodes beyond the limits of the resection at the time of operation.

The remaining 8 patients who have succumbed apparently died of inanition. They illustrate one of the problems in the postoperative management of gastrectomized patients. J.N., a 55 year old colored male, underwent total gastrectomy on December 16 1914, for an extensive carcinoma of the lesser curvature of the stomach with invasion of regional lymph nodes. No distant metastases were found. Two days after operation, atelectasis of the left lower lung field developed, but he recovered quickly in the next 24 hours. Thereafter his course was uneventful. He was started on liquids by mouth on the 4th post-operative day. He tolerated his feedings well and his diet was steadily increased. At the time of discharge from the hospital on the 16th day after operation, he was eating a full soft diet taken in 6 small feedings a day. He had been up and walking about the ward for 5 days and had no complaints. Roentgenography after the ingestion of barium showed the esophagojejunal anastomosis to function satisfactorily. He was discharged in the care of friends who apparently had no regard for his dietary requirements. Eight days later he was returned to the hospital in a comatose condition and died within a few hours. He was said to have taken nothing by mouth after discharge but small sips of water. At autopsy the anastomosis was found to be widely

patent. Scattered microscopic metastases were found in other organs but there was nothing to explain his early death but starvation and dehydration.

F.B. a 60 year old colored man, was operated upon on August 17 1915. Total gastrectomy was performed for an extensive carcinoma which involved the distal one third of the stomach with metastases to regional lymph nodes and extension into the posterior surface of the anterior abdominal wall. His postoperative course was complicated by an attack of acute pancreatitis during which the serum analysis showed 9.9 milligrams per cent reducing substance per milliliter or 540 per cent of average normal (9). He recovered from this attack spontaneously but later partial intestinal obstruction developed. Exploratory laparotomy was performed on the 23d postoperative day when adhesions about a partially obstructed loop of jejunum were freed. Following the second operation his course was uneventful, and at the time of discharge on September 30, 1915, he was taking a full soft diet divided into 6 small feedings a day. His weight was increasing. He was followed thereafter at weekly intervals by Dr. Moses Paulson in the medical outpatient department. His weight increased, his appetite was good, and he followed instructions fairly well. His only complaint was of intermittent edema of the ankles. The total serum protein on November 1 1915 was 6.63 grams per cent. The nonprotein nitrogen was 30 milligrams per cent and serum bilirubin was less than 0.8 milligram per cent. Jejunoscopy on December 12 was essentially negative. He was last seen in the outpatient department on January 11 1916. Six days later he was brought to the accident room to be pronounced dead how

ever a faint cardiac pulsation was heard and intensive supportive therapy was instituted. He improved for a time but died in 24 hours. Permission for autopsy was not granted.

The patient had no relatives and a reliable history of events leading up to this final episode could not be obtained. He had apparently been feeling weak for several days. About 3 days before admission he had fallen without suffering any particular injury but following this accident he stayed in bed. As there was no one to care for him he had eaten practically nothing. His condition grew steadily worse up until the time he was admitted to the hospital. Before therapy was instituted his blood sugar was 20 milligrams and the nonprotein nitrogen 58 milligrams per cent. Five minutes after receiving 50 cubic centimeters of 50 per cent glucose intravenously he responded to verbal stimuli for the first time. It was our belief that the patient died of starvation and dehydration.

The terminal events in these 2 cases were very similar. It was felt that both of these patients would have survived had they been provided with ordinary dietary requirements. During a period of a very few days they had declined from a relatively good general state of health into a moribund condition that failed to respond to intensive therapy. The nutritional reserve of these patients is apparently so small that the absence of an adequate food intake for a short time cannot be tolerated. It is imperative that these patients be seen frequently after operation and any disturbance in nutritional intake be reported immediately. We have recently adopted the rule that unless we can be certain that the care of these patients after returning home will be entirely satisfactory they must remain in the hospital for an extra week beyond the usual discharge date to allow them to gain additional strength. The management of these patients after discharge from the hospital has been supervised by Dr Moses Paulson. The details of the medical and dietary regimen which he has developed, together with the observations made by jejunoscopy, will appear in a subsequent publication.

The survival period of the 10 patients alive at the time of this report ranges from 19 months to 4 months. All of these patients have gained weight although the increase has usually not been great. The weight of none of these patients has equalled his normal weight before the onset of gastric symptoms. The

lack of adequate gain in weight has been rather puzzling for all of the patients have a good appetite and apparently eat well. Careful questioning, however, has disclosed the fact that even after a year and a half, the usual meal is smaller than normal. Too large a meal brings on an uncomfortable feeling of epigastric fullness and hence they limit their intake. 'Between meal' nourishment which is advised, has frequently been omitted particularly after the patients return to work. New diets are being tried at present. Another important factor is the large amount of unabsorbed fat which is excreted in the stool. Recent preliminary metabolic studies in 3 of these cases, 7 months or more after operation conducted by Dr John E. Howard and Mr Lay Fox, confirm the results of Rekers, Pack, and Rhoads of an impaired ability to absorb the fat of the diet. The percentage of fat in the dry stool ranged between 22.5 and 49.0 per cent. As the number and character of the stools have been normal it has been assumed that the dietary fat has been digested but absorption has been inadequate.

In addition to epigastric fullness, 4 patients complain of epigastric and substernal burning usually experienced 15 to 30 minutes after meals. This symptom frequently follows the ingestion of fruit juices. It is temporarily relieved by taking alkalis.

All of the patients operated upon over a year ago have resumed a major portion of their normal occupations. Four of them all men have returned to their regular jobs. The 2 women do housework. One patient 12 months after operation, is able to do only light work at irregular intervals. One patient, 4 months after operation does a limited amount of light work. Two patients have been unable to return to work one 8 months after operation and the other 4 months after operation.

Ferrous iron has been given at regular intervals to all of these patients. Hemoglobin values and red cell counts of the blood of all of them have remained within normal limits. Normal blood prothrombin and bilirubin values have also been found consistently in all of these patients. These studies will be reported in greater detail.

SURGERY GYNECOLOGY AND OBSTETRICS

TABLE III.—PRESENT CONDITION OF SURVIVORS

Name	Postoperative interval	Weight	Appetite	Food capacity	Gastrointestinal symptoms	Stools	Work
J W	9 months	Gained slowly to the under last weight	Good	Must eat small meals	Occasional burning and fullness after meals	Normal r.i.d.	Regular

one of whom survived $7\frac{1}{2}$ months large retroperitoneal masses developed along the aorta, suggesting that the malignant condition had spread to unsuspected lymph nodes beyond the limits of the resection at the time of operation.

The remaining 3 patients who have succumbed apparently died of inanition. They illustrate one of the problems in the postoperative management of gastrectomized patients. J N., a 55 year old colored male, underwent total gastrectomy on December 16, 1944, for an extensive carcinoma of the lesser curve of the stomach with invasion of regional lymph nodes. No distant metastases were found. Two days after operation, atelectasis of the left lower lung field developed but he recovered quickly in the next 24 hours. Thereafter his course was uneventful. He was started on liquids by mouth on the 4th post operative day. He tolerated his feedings well and charge from the hospital on the 16th day after operation. He was eating a full soft diet taken in 6 small feedings a day. He had been up and walking about the ward for 5 days and had no complaints. Recent esophagojejunal anastomosis to function satisfactorily. He was discharged in the care of friends who apparently had no regard for his dietary requirements. Eight days later he was returned to the hospital in a comatose condition and died within a few hours. He was said to have taken nothing by mouth after discharge but small sips of water. At autopsy the anastomosis was found to be widely

patent. Scattered microscopic metastases were found in other organs but there was nothing to explain his early death but starvation and dehydration.

F B a 60 year old colored man, was operated upon on August 17, 1945. Total gastrectomy was performed for an extensive carcinoma which involved the distal one-third of the stomach with metastasis to regional lymph nodes and extension into the posterior surface of the anterior abdominal wall. His postoperative course was complicated by an attack of acute pancreatitis during which the serum analysis showed 9.9 milligrams per cent reducing substance per milliliter of 540 per cent of average normal (9). He recovered from this attack spontaneously but later partial intestinal obstruction developed. Exploratory laparotomy was performed on the 33d postoperative day when adhesions about a partially obstructed loop of jejunum were freed. Following the second operation his course was uneventful, and at the time of discharge on September 30, 1945 he was taking a full soft diet divided into 6 small feedings a day. His weight was increasing. He was followed thereafter at weekly intervals by Dr. Moses Paulson in the medical outpatient department. His weight increased, his appetite was good, and he followed instructions fairly well. His only complaint was of intermittent edema of the ankles. The total serum protein on November 1, 1945 was 6.63 grams per cent. The nonprotein nitrogen was 30 milligrams per cent and serum bilirubin was less than 0.8 milligram per cent. Jejunoscopy on December 13 was essentially negative. He was last seen in the outpatient department on January 11, 1946. Six days later he was brought to the accident room to be pronounced dead, how

ever a faint cardiac pulsation was heard and intensive supportive therapy was instituted. He improved for a time but died in 24 hours. Permission for autopsy was not granted.

The patient had no relatives and a reliable history of events leading up to this final episode could not be obtained. He had apparently been feeling weak for several days. About 3 days before admission he had fallen without suffering any particular injury but following this accident he stayed in bed. As there was no one to care for him he had eaten practically nothing. His condition grew steadily worse up until the time he was admitted to the hospital. Before therapy was instituted his blood sugar was 20 milligrams and the nonprotein nitrogen 58 milligrams per cent. Five minutes after receiving 50 cubic centimeters of 50 per cent glucose intravenously he responded to verbal stimuli for the first time. It was our belief that the patient died of starvation and dehydration.

The terminal events in these 2 cases were very similar. It was felt that both of these patients would have survived had they been provided with ordinary dietary requirements. During a period of a very few days they had declined from a relatively good general state of health into a moribund condition that failed to respond to intensive therapy. The nutritional reserve of these patients is apparently so small that the absence of an adequate food intake for a short time cannot be tolerated. It is imperative that these patients be seen frequently after operation and any disturbance in nutritional intake be reported immediately. We have recently adopted the rule that unless we can be certain that the care of these patients after returning home will be entirely satisfactory they must remain in the hospital for an extra week beyond the usual discharge date to allow them to gain additional strength. The management of these patients after discharge from the hospital has been supervised by Dr Moses Paulson. The details of the medical and dietary regimen which he has developed together with the observations made by jejunoscopy, will appear in a subsequent publication.

The survival period of the 10 patients alive at the time of this report ranges from 19 months to 4 months. All of these patients have gained weight although the increase has usually not been great. The weight of none of these patients has equalled his normal weight before the onset of gastric symptoms. The

lack of adequate gain in weight has been rather puzzling for all of the patients have a good appetite and apparently eat well. Careful questioning however, has disclosed the fact that even after a year and a half the usual meal is smaller than normal. Too large a meal brings on an uncomfortable feeling of epigastric fullness and hence they limit their intake. Between meal nourishment, which is advised, has frequently been omitted particularly after the patients return to work. New diets are being tried at present. Another important factor is the large amount of unabsorbed fat which is excreted in the stool. Recent preliminary metabolic studies in 3 of these cases 7 months or more after operation conducted by Dr John L. Howard and Mr Lay Fox confirm the results of Rekers, Pack and Rhoads of an impaired ability to absorb the fat of the diet. The percentage of fat in the dry stool ranged between 22.5 and 49.0 per cent. As the number and character of the stools have been normal it has been assumed that the dietary fat has been digested but absorption has been inadequate.

In addition to epigastric fullness 4 patients complain of epigastric and substernal burning usually experienced 15 to 30 minutes after meals. This symptom frequently follows the ingestion of fruit juices. It is temporarily relieved by taking alkalis.

All of the patients operated upon over a year ago have resumed a major portion of their normal occupations. Four of them, all men, have returned to their regular jobs. The 2 women do housework. One patient, 12 months after operation, is able to do only light work at irregular intervals. One patient, 4 months after operation does a limited amount of light work. Two patients have been unable to return to work one 8 months after operation and the other 4 months after operation.

Ferrous iron has been given at regular intervals to all of these patients. Hemoglobin values and red cell counts of the blood of all of them have remained within normal limits. Normal blood prothrombin and bilirubin values have also been found consistently in all of these patients. These studies will be reported in greater detail.

SUMMARY

In the past, total gastrectomy has usually been reserved for the treatment of those malignant lesions of the stomach without distant metastases which could not be locally removed by subtotal resection. The high mortality rate of the procedure and the incidence of serious postoperative complications together with the uncertainties of digestion and metabolism in the absence of the stomach, have restricted the use of total gastrectomy. If these objections can be obviated undoubtedly block excision of the stomach and regional lymph nodes should be the most effective means of treating neoplasms of the pyloric and fundic regions of the stomach. The present series of 20 total gastrectomies with 2 operative deaths, together with the recent reports of other writers, indicates that the operative mortality of total gastrectomy is no longer prohibitive.

The available information concerning the digestion and metabolism of gastrectomized patients has been limited and uncertain. The postoperative study of these patients 7 of whom have now survived for a year furnishes additional evidence that such patients can maintain a fairly satisfactory nutritional state with special medical and dietary supervision. Six of these patients have returned to their former occupations. All of the patients now surviving have gained weight. The gains in weight have not been large however ranging from 2 to 12 pounds. The hemoglobin value in all cases is within the normal range. All of the patients are having from 1 to 3 normal bowel movements a day although preliminary metabolic studies in 3 patients indicate an impairment of absorption of the dietary fat. They uniformly have a good appetite and are now taking a full diet divided into 4 to 6 meals a day. Recent roentgenograms, in all cases but 1 show a normal passage of barium through the anastomosis and remaining intestinal tract. One patient has a slight delay in the passage of barium through the anastomosis.

The lack of adequate gain in weight, the excretion of abnormal amounts of fat in the

stools the slow return of normal muscular strength and the persistence of occasional attacks of abdominal fullness and epigastric burning are still problems to be solved, possibly by new surgical procedures or by improved postoperative medical management.

CONCLUSIONS

Total gastrectomy offers the most effective means of eradicating gastric carcinoma of the pyloric antrum and fundus. Since it is possible to perform total gastrectomy with a mortality rate of less than 10 per cent, and since the evidence at present indicates that gastrectomized patients maintain a fairly satisfactory nutritional state, the more frequent use of the procedure is recommended. Certain lesions that would be considered inoperable if only subtotal gastric resection were employed may be adequately treated by total gastrectomy. Malignant lesions of a less extensive nature should be removed by total gastrectomy if adequate excision of the involved stomach and regional lymph nodes by subtotal resection is considered a doubtful undertaking.

Gastrectomized patients present problems associated with adequate intake and absorption of food sometimes persisting for months after operation, which at present prevent the recommendation of the procedure as the operation of choice for all malignant tumors of the stomach which are amenable to surgical treatment.

COMPLICATIONS FOLLOWING THE USE OF COTTON AS SUTURE MATERIAL

R. C. DERBYSHIRE, M D Albuquerque, New Mexico

THE use of spool cotton as suture material in surgery is now well established and has been employed routinely in many outstanding surgical clinics in this country for several years. Ever since the appearance of the results of the experimental work of Meade and Ochsner (7) the reports in the literature have been uniformly enthusiastic in their support of cotton. Complications following its use have been so rare as to warrant their publication as individual case reports (1). Cotton as suture material was first used routinely in all my cases early in 1943 and it seemed entirely satisfactory, as I had anticipated. However after a few months, complications which were considered directly attributable to the suture material began to be encountered with sufficient frequency to prompt me to investigate the cases with a view to determining the incidence and causes of these complications. In the cases in which the wounds healed without complications I as well as others had noted that the healing and scars were so far superior to those in which catgut had been used, that it was considered undesirable to discontinue the employment of cotton without investigation.

After the study had been begun more and more surgeons were found who objected to the use of cotton for various reasons. Most of them however had had little personal experience in its use and were not sufficiently familiar with specific cases in which it had proved unsatisfactory to warrant publication of their results. A notable exception to this group was Key who stated that he had given cotton a trial only to abandon it and return to the use of catgut. He particularly objected to its use in orthopedic operations where it was buried over a gliding surface such as a joint. Although certain writers have mentioned instances in which it has been extruded from

wounds, this complication is not considered serious because it has not been accompanied by the chronic draining sinuses so commonly encountered when other types of nonabsorbable sutures have been employed.

The main advantages that have been claimed for cotton are its pliability, decreased tissue reaction, adequate tensile strength, high coefficient of friction and stability on exposure to heat and moisture (2, 3, 5, 6, 8, 9). Another distinct advantage is the fact that it encourages the surgeon to be gentle in the handling of tissues. All of these claims are perfectly logical and just. However extravagant claims have been made and it is thought that one writer was slightly overenthusiastic when he attributed the lower post-operative febrile reaction in a group of patients who had undergone herniorrhaphies to the fact that they had been repaired with cotton (10).

It has been repeatedly pointed out by Ochsner and others that the successful use of cotton depends upon strict observance of the tenets of Halsted which are as follows:

- 1 Use interrupted sutures only
- 2 Never use coarse suture material.
- 3 Never bridge over a dead space as a cord subtends an arc.
- 4 Use transfixion sutures in ligation as finer material can be used in this way
- 5 Use a greater number of fine stitches rather than a few coarse ones.
- 6 Avoid the combined use of absorbable and nonabsorbable sutures.

METHODS AND MATERIAL

The present report is based upon 372 operations of various types performed in three different hospitals in which cotton was used as suture material either alone or in conjunction with catgut. The only cases in which the two materials were used together were in laparotomies in which the peritoneum was sutured

From the Department of Surgery Lovelace Clinic.

TABLE I.—IMMEDIATE POSTOPERATIVE COMPLICATIONS

Case No	Operation	Type of complication
2	Thyroidectomy	Severe infection
7	Herniorrhaphy	Superficial infection
10	Appendectomy	Severe infection
10	Herniorrhaphy	Hematoma
41	Leg amputation	Superficial slough
51	Kistectomy	Deep abscess
70	Closure of colostomy	Deep abscess
81	Appendectomy	Slight infection
9	Herniorrhaphy	Maceration of skin
95	Appendectomy	Severe infection
	Cholecystectomy	Superficial infection
14	Right colectomy	Wound disruption
5	Cholecystectomy	Wound disruption
23	Tenorrhaphy	Superficial infection
25	Leg amputation	Superficial infection
37	Open reduction of compound fracture	Superficial infection
59	Tenorrhaphy	Superficial infection
7	Ramstsch	Small stitch abscess
172	Thyroidectomy	Severe wound infection
202	Open reduction	Severe wound infection
9	Appendectomy	Deep wound infection with extensive slough
57	Herniorrhaphy	Small hematoma
180	Herniorrhaphy	Superficial infection
175	Herniorrhaphy	Superficial infection
204	Closure of perforated ulcer	Deep abscess
112	Gastrectomy	Deep abscess
147	Subhygo-clopic seton	Intestinal obstruction, severe infection
141	Appendectomy	Deep abscess
170	Herniorrhaphy	Superficial infection

with continuous chromicized catgut, the remainder of the structures with interrupted cotton. Ordinary long fiber spool cotton sterilized by autoclaving was employed in every case. Only three sizes were used. No. 60 for ligature of small vessels, No. 30 for suture of the deep fascia and ligature of larger vessels and occasionally heavy crochet cotton for ligature of still larger vessels. In the type of operations performed it was seldom necessary to use the heavy cotton. The tenets of Halsted were followed except for the combined use of

absorbable and nonabsorbable sutures as mentioned.

The series included 34 different types of operations, of which 158 were laparotomies, 74 orthopedic procedures of various types, and the remainder herniorrhaphies, thyroidectomies, repair of deep traumatic wounds, kidney operations, mastectomies, and excision of subcutaneous tumors. Cotton was used indiscriminately whether or not the wounds were infected or contaminated.

The patients were carefully observed for from 4 to 18 months. The original wounds were classified as either clean or contaminated. A contaminated wound is defined as one in which there was previous soiling from outside sources or in which an obviously infected organ such as a perforated appendix was removed. Postoperative wound complications were carefully watched for and the most trivial ones reported (Table I). There were 311 (83.6 per cent) clean and 61 (16.4 per cent) contaminated wounds. The complications ranged in severity from complete disruption and deep abscesses to small hematomas and maceration of the skin edges.

There were 29 cases (7.7 per cent) with early postoperative complications, 15 of which were severe, 14 trivial. The most serious early complication, wound disruption occurred in 2 cases. These are interesting in that this complication is seldom encountered when wounds have been sutured with cotton. Both of these instances occurred in gravely ill patients, one having undergone a one stage resection of the right colon for carcinoma, the other a cholecystectomy for a ruptured gall bladder with generalized bile peritonitis. Secondary suture with through-and-through silk sutures was carried out in each case with uneventful healing. The appearance of the wounds at the time of secondary closure was interesting in that very little cotton could be seen and the small amount present was fragmented. It is thought that this complication cannot be solely attributed to the suture material as there were obviously several other factors responsible which are usually found in all cases of wound disruption regardless of the type of suture material employed. Further reference to Table I will reveal that the remainder of

the early postoperative complications were in no respect unusual and the same that might be seen in any similar series of operations.

Table II shows the late complications encountered. In this class were also included all of the complications no matter how trivial. It was considered of particular importance to note whether or not any cotton knots were extruded from the depths of the wounds. The occasional extrusion of a cotton knot, if it did not interfere with wound healing, was not considered serious. However, the patient frequently attaches undue significance to this and in 2 cases which were not considered serious or complicated from the standpoint of healing there were threats of litigation. It may seem strange to some readers that there were such threats even though the eventual wound healing was retarded little if any. However in this region for many years non-absorbable sutures have never before been used on a large scale and the patients are educated to believe that all deep sutures should be absorbed.

The cases showing late complications naturally fall into two groups, the mild and the serious. The former has been explained. If a large number of knots are extruded or if the suture material was considered definitely to interfere with the healing of the wound the complication must be regarded as serious. All of those cases in which it was thought that the suture material alone was not responsible for the difficulty were excluded from this group. According to this criterion it is seen that of the 17 cases with late complications (4.5 per cent) 9 (2.4 per cent) were considered serious. Further reference to Table II reveals that the complications often did not appear until several weeks or months after the wound had healed. At the present time all of the wounds are healed, even though exploration was necessary in 3 cases which will be considered in some detail below.

An attempt was made to discover whether or not any common denominator could be applied to the cases with late complications. It was discovered early in the study that the cases did not follow any definite pattern in regard to infection. For example there were several perfectly clean wounds from which

TABLE II —LATE COMPLICATIONS

Case No.	Operation	Type of complication	Time of appearance
3	Thyroidectomy	Extrusion of 1 knot	4 months
4	Thyroidectomy	Extrusion of 2 knots	months
19	Mastectomy	Extrusion of knot	6 weeks
74	Closure of colostomy	Extrusion of many knots, healed after 3 months	weeks
83	Appendectomy	Sinus for 4 months; exploration necessary	Immediately
85	Urethrolithotomy	Sinus for 3 months	Immediately
9	Hemiorrhaphy	5 knots extruded	5 weeks
95	Appendectomy	Drained for 4 months; many knots extruded	Immediately
9	Appendectomy	3 knots extruded	4 weeks
33	Open reduction	Many knots extruded	6 weeks
123	Tenorrhaphy	knots extruded	3 weeks
127	Open reduction	Drained 4 months; many knots extruded	3 weeks
130	Tenorrhaphy	knots extruded	weeks
173	Thyroidectomy	Draining sinus 5 months, exploration necessary	week
83	Hysterectomy	Drainage for 6 months, exploration necessary	months
9	Appendectomy	knots extruded	month
230	Thyroidectomy	knot extruded	3 months

cotton was extruded or had to be removed at a later date after healing had progressed uneventfully. On the other hand there were several patients with perforated appendices and considerable peritonitis which healed uneventfully. One of the most striking of these was in a patient with a perforated appendix with massive fecal leakage into the peritoneal cavity. His general condition was complicated by rather severe diabetes. Cotton has also been used to close colostomies without causing difficulty.

Of the 17 cases with late complications 9 were originally classified as clean wounds. Of these, 2 developed severe infections post-operatively. If these are added to the cases which were originally contaminated or infected, it is seen that there is a total of 10 cases in which infection was a conspicuous feature.

The 9 cases with serious late complications are naturally of the greatest interest and will

be considered in some detail. In all of these draining sinuses appeared at various times following operation and they all had one factor in common they did not heal until all of the cotton had been removed, either by being extruded spontaneously or by surgical intervention. In 3 cases it was necessary to explore the wounds, remove many cotton sutures from the deep fascia and resuture them with catgut. This was followed by prompt healing in each instance. Two of the wounds had been grossly infected, one operation having been performed for a perforated appendix with considerable peritonitis, the other a thyroidectomy which was followed by a deep abscess. The third case, a total hysterectomy was perfectly clean, healed by first intention with a minimum of reaction remaining healed for 2 months, at the end of which time two sinuses appeared. Many knots were extruded or were removed with forceps but drainage continued. Consequently at the end of 5 months, it was necessary to explore the sinuses and remove the remaining sutures in the deep fascia. This was followed by prompt healing.

During the latter part of the period comprising the study it was thought that infection was the commonest cause of difficulty and the use of cotton was discontinued in cases in which infection or contamination were present.

The patients were also examined with a view to discovering whether or not cotton was unsuitable for any particular type of wound. In the 4 most common types of operation—laparotomies of all types, orthopedic procedures, thyroidectomies, and herniorrhaphies the incidence of late complications was noted. Out of 158 laparotomies there were 6 complications (3.8 per cent). In 74 orthopedic procedures there were 2 complications (2.7 per cent). In 46 herniorrhaphies there was 1 (2.2 per cent). In 32 thyroidectomies there were 3 (9.3 per cent). When broken down in such a manner it is acknowledged that the series of operations is entirely too small from which to draw any definite conclusions. But here again, with the exception of the thyroidectomies, infection seems to be the only factor that appears with any degree of consistency whatever. The question as to whether or not the quantity of cotton buried in any one

wound will have any effect upon the healing also arose. If this were true, one would expect to find more difficulty with the thyroidectomies than with any of the other types of operations, as much more cotton is used in them. This was not found to be the case.

The series was arbitrarily divided into three parts on a chronological basis. In the first one third there were 9 complications. In the second, 7 while in the last one third there was only 1. One possible explanation for this is that the writer became more and more adept in the use of cotton and more meticulous in his technique with the passage of time. Even though he had had previous experience in the use of nonabsorbable suture material in the form of silk, he had become thoroughly accustomed to the use of catgut, which had been employed for several years. Although every effort was made to carry out each procedure as meticulously as possible early in the series it was found that there was a natural tendency to use cotton in a fashion similar to that in which silk had been used. It was frequently found that too much tissue had been included in a ligature, for example. However the better results in the last group may be partly due to the fact that no contaminated cases were included. The decreasing incidence of complications might also be due to the fact that in the last group insufficient time had elapsed for all of them to appear. But in the vast majority of cases the complications occurred within the first 4 months and all of the cases were observed for at least that length of time.

DISCUSSION

While it is not considered that all of the causes of complications have been found, from the analysis presented, it seems that the most conspicuous single factor in the complicated wounds is infection. Although it was a factor in only a slight majority it is regarded as sufficiently important to cause the writer to feel that cotton is not the suture material of choice in such cases, in spite of many opinions to the contrary. Emphasis must also be placed upon surgical technique in the use of this material and it is considered that the results, at least in the clean cases, should show further

improvement. It is thought that an incidence of serious postoperative complications due to suture material of 2.4 per cent is entirely too high, and the 3 cases in which the deep sutures had to be removed would be sufficient to cause many surgeons to abandon cotton entirely. A word of warning is believed in order to the surgeon who has been accustomed to the use of catgut and considers adopting cotton.

CONCLUSIONS

1. A series of 372 operations in which cotton suture material was employed is presented.
2. There were 17 cases (4.5 per cent) with late complications attributable to the suture material which is considerably higher than the incidence encountered in the literature. Of these, 9 were considered serious and 8 mild.
3. Two early complications in the form of wound disruption were encountered which is very rare according to the literature.
4. Infection did not seem to be present frequently enough to attribute all of the bad results to it.

5. Complications were present more frequently in the earlier than in the later cases in the series, and it is suggested that this may be due to improvement in technique in the later cases as well as to the fact that the use of cotton was finally given up in obviously infected or contaminated cases.

6. While cotton is still considered an excellent suture material contrary to general opinion it is not entirely without hazards and has definite limitations.

THE EVOLUTION OF ADENOMAS OF THE LARGE INTESTINE AND THEIR RELATION TO CARCINOMA

ELSON B. HELWIG M.D., St. Louis, Missouri

THE present day active search for the smallest tumors which may be recognized as malignant has added a new importance to many lesions previously considered insignificant. During the last few years there has been an increasing effort on the part of pathologists to recognize carcinomas in its preinvasive stage. By repeated biopsies Schiller was able to show that certain lesions of the cervix were followed eventually by an invasive carcinoma. Broders applied the phrase *carcinoma in situ* to describe this noninvasive stage of carcinomas of glandular and of squamous cell origin. Both Verge and Dukes observed the presence of carcinoma in polypoid adenomas of the large intestine a picture which would appear to correspond to the *carcinoma in situ* of Broders. Moreover the literature attests that this picture has been noted by many workers. Nevertheless the exact relation of adenomas to carcinomas of the large intestine has remained controversial.

Adenomas constitute the great majority of polyps occurring in the large intestine (10). Confusion in the literature has resulted from the different interpretation of the term polyp. By some authors, the term polyp is used to designate any sessile or pedunculated benign tumor arising in the mucosa or wall and projecting into the lumen of the intestine. While this interpretation indicates the gross appearance of the tumor it does not signify the exact pathologic type. On the basis of histologic examination the generic classification of polyps may be divided into several different specific types of tumors such as adenomas, lipomas, leiomyomas, and carcinoids. By other authors the term polyp has been considered synonymous with adenoma. In order

to avoid this confusion of terminology it would seem best to designate these tumors according to their specific structure. In this paper the term adenoma is used to designate either a sessile or pedunculated benign tumor of glandular origin. In accord with this restricted interpretation of the term adenoma, I have excluded from this study all other types of tumors, hemorrhoids, fibrous tags, and lesions obviously the result of infection.

The problem of the relation of adenomas to carcinomas of the large intestine has usually been investigated by one of two different methods. First, information about adenomas has come from observations made on patients at frequent intervals. While this method of study is advantageous, it is also inconvenient. Furthermore, it is not an ideal therapeutic procedure to follow the course of an adenoma over a period of time and determine whether a transition from benignancy to malignancy occurs. The second method by which information has been gained has come from the observation in adenomas of histologic changes commonly recognized as diagnostic of carcinoma. Many of the investigations in which adenomas have been examined for histologic foci of carcinoma have been undertaken on small segments of the colon removed at surgical operation. Other investigations, in which there has been no concerted effort to determine the exact occurrence of adenomas or to examine all of them carefully, have been carried out on colons removed at autopsy. It seemed that a more definite understanding of the relation of adenomas to carcinomas of the large intestine could be gained by a careful determination of the incidence of adenomas at autopsy and the analysis of each adenoma for the presence or absence of histologic changes commonly recognized as diagnostic of carcinoma.

MATERIALS AND METHODS

The present report is based upon a study of 1460 consecutive autopsies in which the entire large intestine was carefully examined in the fresh state. All sessile and pedunculated mucosal elevations together with the contiguous wall of the colon were removed and fixed in 4 per cent formaldehyde. The site of each lesion was noted and its distance from a specific landmark was recorded. After fixation notes and drawings were made of each lesion. If a lesion was large it was divided one or more times along a plane perpendicular to the mucosa. Specimens were then embedded in paraffin in such a manner that the plane of the section was at a right angle to the plane of the mucosa. At intervals throughout each block, step and serial paraffin sections stained with hematoxylin and eosin were prepared. Unstained sections contiguous with the stained sections were saved until after the stained sections were observed. Additional sections were prepared when deemed necessary. The microscopic findings were then noted and compared with the gross appearance.

CLASSIFICATION OF ADENOMAS

A great deal has been written about the classification of adenomas of the large intestine (2 5 7 8 13 16 17 21). Most of the proposed classifications have been based upon (1) apparent etiologic factors such as ulcerative colitis (2) clinical features such as the singularity or multiplicity of the tumors and the age of the patient, and (3) the character of the morphologic and histologic structure of the tumor.

The adenomas studied in the present series of cases have not yielded evidence to support the concept of an associated inflammation as the inciting agent of the adenomas. Although most of the more common types of colitis were encountered in the present series of autopsies only one example of the association of colitis and adenomas was observed. In the colon of a 67 year old man, a single adenoma and amebic ulcers were present. It would appear from this series that any relation between the presence of some form of colitis and adenomas is purely coincidental.

The clinical picture of familial adenomatosis or multiple polyposis of the large intestine is well established. However, it is impossible to determine any fundamental differences in adenomas occurring in familial adenomatosis and those occurring singly. The gross and microscopic features of adenomas noted in the one example of familial adenomatosis in this series could be duplicated in any number of colons containing one or only a few adenomas.

The literature contains many references to classifications based upon either or both the macroscopic and microscopic appearance of adenomas. It is claimed that the contour of the tumor and the regularity or irregularity of the surface are useful criteria regarding classification. Much importance has been attached to the microscopic appearance of the epithelium and to the connective tissue framework. It seems doubtful that any significance such as was suggested by Hauser can be attributed to the amount of degenerated epithelium. In the present series degenerated epithelium occurred in adenomas in an indiscriminate manner. Likewise the separation of adenomas into three groups as proposed by Fitzgibbon and Rankin (8) and others (9) seems to be of questionable usefulness. These authors, on the basis of the histologic picture felt able to determine that certain adenomas were destined for a long and benign course. Such a degree of faith in the interpretation of a histologic section does not seem warranted. In the present series many of the adenomas when studied by step and serial sections did not show a uniform cytologic and histologic picture. No evidence could be adduced that any particular group of adenomas would maintain a constant benign course. It does not seem justifiable to predict that a selected group of adenomas will not contain a focus of carcinoma at some future date. These same authors also were presumably able to determine the age of an adenoma by the microscopic appearance. The observations in the present study did not give any clue as to the age of an adenoma. It seems doubtful that the age of an adenoma can be determined except by observation of the tumor in a patient over a period of time.

On the basis of the present study no distinguishing morphologic and histologic characteristics which would seem to warrant a complex classification of adenomas were noted. In all instances the adenomas appeared basically similar and no practicable significance could be attached to minor variations of structure and cells.

MORPHOLOGY AND EVOLUTION OF ADENOMAS

The gross appearance of adenomas has been described many times. In the present series the tumors varied in size from 1 millimeter to 9 centimeters in diameter. The smaller tumors in some instances occurred on the summits of mucosal folds and at other times arose from the flat mucosa. There did not appear to be any definite pattern for this phenomenon since intestines with multiple adenomas were likely to show involvement of both sites. Moreover a comparison of those adenomas of similar size which were situated on the summits of folds with those arising from the flat surface frequently showed a longer pedicle on the former. This picture suggests that the site of the adenoma may influence the development of the pedicle. Those adenomas situated on a mucosal fold would be more exposed to peristaltic action of the intestine.

It is common practice to describe adenomas as pedunculated or sessile. Many of the tumors present an obvious pedicle and may be correctly termed pedunculated. The group of tumors referred to as sessile do not present such an obvious picture. These tumors are commonly hemispherical in shape and on the basis of the external configuration appear sessile. However in most instances, a midsagittal section through the tumor reveals a short central stalk with tumor overhanging the margins like an umbrella. In reality many adenomas with the appearance of sessile tumors are actually pedunculated and only a few tumors are truly sessile. Even when an adenoma covers a large surface and appears sessile there may be numerous individual stalks supporting closely approximated polypoid projections.

The contour of the adenomas may be regular lobulated or villous. Both the pedicle and the tumor frequently are flattened in one

dimension. Not only may different adenomas in one colon exhibit various configurations, but occasionally a single adenoma may show diverse forms of contour. In general the smaller tumors are more likely to show a regular outline and the larger adenomas a definitely lobulated or villous form. Likewise the smaller tumors tend to be gray in color and the larger tumors grayish red or red. However these tinctorial qualities are not constant and a fair proportion of the tumors will exhibit both red and gray foci. The color is determined by the richness of the vascular supply by the degree of congestion and by foci of hemorrhage, inflammation, and ulceration.

Because of the protean histologic structure of adenomas it is difficult to describe any particular picture as typical. The small tumors are disposed to have a more simple framework than are the larger ones. Usually this consists of a single connective tissue core with or without an extension of the muscularis mucosae into the stalk. When the adenomas are minute, a definite connective tissue stalk may be absent. In such instances the histologic picture is primarily one of epithelial hyperplasia. The epithelial hyperplasia brings about either an increase in the size of the glands or in the number of glands or both. Usually there is no appreciable disposition to stratification of the cells or to papillary infolding. The epithelial cells may or may not be distended with mucus but otherwise are not particularly abnormal. An essentially similar picture has been described by Dukes, who observed patches of epithelial hyperplasia in the vicinity of carcinomas of the colon. Dukes considered these patches of epithelial hyperplasia to be the first step in the formation of adenomas. The location of the epithelial hyperplasia has been thought by Bergen-Cromar and Dixon (1) to be determined by the site of the lymphoid follicles in the intestine. According to these authors a subclinical inflammatory process produces a rupture of the lymphoid follicles, and the subsequent repair results in an isolation of a portion of epithelium by a ring of lymphoid tissue. This process may result in the formation of an adenoma or because of a change in the envi-

environment of the cells give way to malignant neoplasia. This theory is hardly tenable in the light of the observations in the present study. Microscopic examination of the smallest adenomas disclosed some with lymphoid follicles situated in the stroma beneath the epithelial hyperplasia and others without lymphoid nodules. If the lymphoid nodules are an essential factor in the evolution of the adenoma then they should be found in all examples. Moreover, lymphoid nodules undergo hyperplasia in other organs such as the appendix, small intestine, and thyroid and are not associated with the development of adenomas. As will be brought out subsequently, adenomas of the large intestine are less common in the negro than in the white race although there is no evidence that negroes have fewer lymphoid nodules or less clinical or subclinical inflammation of the large intestine. The lymphoid nodules normally are located internal or external to the muscularis mucosae and in some instances partially obscure it. There is no constant location of the nodules, when present, relative to the epithelial hyperplasia. They may appear either directly beneath the epithelial hyperplasia or at the margin. This suggests that there is no direct relation between the site of the lymphoid nodule and the development of the adenoma. It is not surprising that some adenomas show one or more lymphoid nodules in the immediate vicinity. The adenomas are subjected to peristaltic action and frequently show infiltration of inflammatory cells, hemorrhage and deposits of hemosiderin. Lymphoid nodules are normally present in the large intestine and large lymphoid follicles with secondary nodules commonly occur in inflammation. Thus a subadjacent prominent lymphoid nodule might be expected to occur as a result of inflammation within the tumor. The lymphoid nodules occasionally observed at the margin of lipomas and carcinoids of the colon probably occur for the same reason. On the basis of this evidence it seems more logical to conclude that the lymphoid nodules are not an important factor in the mechanism of development of adenomas but are coincidental and undergo hyperplasia as the result of the presence of the tumor.

As the adenomas increase in size the supporting connective tissue structure tends to become more complex. In the largest tumors it is common to observe not only a central stalk but also a number of branches which support the polypoid or villous processes. The central stalk and branches are comprised of connective tissue and in some tumors contain strands of smooth muscle. The smooth muscle may or may not be continuous with the muscularis mucosae. The connective tissue frequently shows a variation in the degree of cellularity, not only among all adenomas but in different fields of a single tumor. The stroma is sometimes dense and hyalinized and at other times tenuous and cellular. The extent of the vascularity of the stalk is also variable. In most adenomas the larger tumors, in particular one or more large blood vessels is present. Occasionally the walls of the arteries are thickened and are the seat of hyalinization. Some adenomas contain arteries and veins occluded by thrombi. All stages of organization are represented among the thrombi. In some instances the thrombi appear to be secondary to the inflammatory process. This is especially evident when the involved area is limited to the superficial or exposed segment of the tumor. In other examples the thrombi are not accompanied by an appreciable inflammatory reaction. It is conceivable that the thrombi in these adenomas are the result of trauma or twisting of the pedicle of the tumor.

The architectural pattern of the glands forming the larger adenomas may appear essentially similar to that of the small tumors previously described. More frequently, the glands in the larger tumors exhibit abnormalities such as elongation, dilatation, branching and papillary infolding. The character of the epithelial cells lining the glands shows little change from normal. The cells are usually tall and columnar sometimes have an elongated and compressed appearance and may or may not be predominately of the mucous type. The nuclei are moderately chromatic and usually do not show large nucleoli. There is a distinct tendency for the nuclei which are sometimes elongated to occupy the basal portion of the cells. Mitotic figures may be

frequently encountered. Stratification of the epithelial cells is uncommon, and there is a definite line of demarcation of the epithelial cells from the contiguous stroma. If the tumor is pedunculated normal appearing mucosa commonly covers the pedicle or base of the stalk.

Swinton and Warren have stated that adenomas usually show no evidence of inflammatory reaction other than slight lymphocytic infiltration at the base. This observation is contrary to the observations made in the present study. I have found that adenomas, the larger ones in particular contain inflammatory cells, including lymphocytes, plasma cells, monocytes, and neutrophils and eosinophilic polymorphonuclear leucocytes. Several tumors contained foci of acute inflammation, small abscesses and ulceration. Serial and step sections of a single adenoma may disclose acute inflammation in some sections and not in others. It is possible that some of the dense connective tissue within adenomas represents the former sites of inflammation. That the adenomas are subjected to severe trauma is verified by the frequent observation of hemorrhage and intracellular and extracellular deposits of hemosiderin within the stroma of the tumors.

Many authors have attributed the development of adenomas in the large intestine to some form of antecedent inflammation. In

the present study it was rarely possible to demonstrate gross or histologic changes of a previous inflammation in the mucosa or wall of the intestine. This observation does not deny that small or minor foci of inflammation had not previously occurred followed by complete repair or the evolution of an adenoma—neither does it support such a concept. However it does seem unlikely that an inflammatory process such as ulcerative colitis could regress without leaving evidence of chronic inflammation, atrophy or fibrosis. Since one person in five who reaches the age of 60 has an adenoma of the large intestine it is reasonable to expect some people with adenomas to reveal a past history of colitis. A previous history of colitis should not then necessarily implicate the colitis as the etiologic agent of adenomas. The observations in the present study coincide with the opinion of Swinton and Warren that adenomas of the large intestine are true tumors and are not the result of diffuse inflammatory processes.

THE INCIDENCE OF ADENOMAS

The large intestine in each of 1,460 consecutive autopsies was examined. Of this number 139 or 9.5 per cent contained adenomas. After 1 case of familial adenomas was excluded the remaining 138 specimens contained 372 tumors. Four of the tumors were unsatisfactory or unavailable for detailed mi-

oscopic study and were considered as benign adenomas.

In Table I the incidence of adenomas of the large intestine of 1 279 white patients is given and in Table II similar figures are presented for 181 negro patients.

The incidence of adenomas in the 1 279 white patients was 10.4 per cent. When the incidence is studied by age groups a fairly constant progressive increase is noted above the age of 30 in both sexes. The peak incidence was reached in the eighth decade when 25.8 per cent of the men and 20.5 per cent of the women showed adenomas. In all decades above the third slightly more men than women had adenomas. This observation although not so pronounced is in agreement with the results of Lawrence who noted that more white males over 40 years of age had adenomas of the colon than did white females by the proportion of 1.6:1.

The number of negro patients examined (181) is admittedly small. The overall incidence of adenomas in this group was 2.7 per cent compared with 10.5 per cent in the white patients. If only those patients over 30 years of age are included the incidence in the negro

race was 3 per cent compared with 16 per cent in the white race. From these figures it is evident that at least in the older age groups there is a greater disposition to the development of adenomas among the white race than among the negro race. Lawrence also noted a higher incidence in the white race but not such an appreciable difference.

In 80 of the 139 cases there were single adenomas and in the remaining cases two or more tumors were noted. Saint noted that multiple tumors were slightly more common than were single tumors but Lawrence observed a predominance of single tumors.

From Table III it is apparent that an individual 35 years of age with adenomas has about the same chance of having multiple tumors as does the person 75 years old. However multiple adenomas are more common in older people because the incidence of adenomas is greater in older people. This observation would indicate that in many instances the factors initiating the development of adenomas act on multiple sites at about the same time.

The number of female patients—24—with single adenomas (63 per cent) is slightly greater than the number of male patients—

Fig. 5.

56—with single tumors (55 per cent) Conversely more men—45 (45 per cent)—than women—14 (37 per cent)—have multiple tumors.

The sites of adenomas are shown in Table IV. In 80 of the 139 large intestines the adenomas occurred singly. However 20 of the 59 intestines with multiple tumors showed localization of the tumors to one segment and in 10 more instances the distribution of the tumors was confined to two contiguous segments such as the sigmoid colon and rectum.

or cecum and ascending colon. Thus in 100 of the 139 intestines the tumors were localized to one segment and in an additional 10 examples the tumors were localized to two contiguous segments. In the other 29 intestines the adenomas were scattered indiscriminately throughout though at times more tumors were concentrated in one segment than in another. Thus in the group of tumors without localization 9 of 12 tumors in the transverse colon came from only two intestines.

In a previous paper (10) I have shown that adenomas of the colon are more frequent than adenomas of the rectum and that the sigmoid colon is the most common site of adenomas in the large intestine. As noted in Table IV this latter observation holds true whether there are single tumors, multiple tumors localized to one site or multiple tumors with a wide spread distribution. After taking into consideration that many of the groups in Table IV are small and that the ratio of men to women examined in this series is 7:7 there is a general indication that the incidence of adenomas in men is greater than that in women in all sites of the large intestine regardless of singularity or multiplicity of tumors.

RELATION OF ADENOMAS TO CARCINOMA

In order to acquire further knowledge on the relation of adenomas to carcinoma of the

large intestine, step and serial histologic sections of each tumor and the contiguous wall were analyzed. From these histologic observations it was clear that many adenomas exhibited minor variations in structure in different parts rather than a homogeneous picture. Furthermore a few adenomas contained a focus or foci which resembled the structure of carcinoma. These adenomas with foci of carcinoma were considered to represent the

transition stage from benignancy to malignancy.

The establishment of the transition from simple adenoma to carcinoma is relatively difficult. In the manifest or unquestioned carcinoma the diagnosis is readily established by the invasion of the wall of the intestine. In addition to the invasion of the wall the carcinoma is usually characterized by the formation of irregular glands a certain de-

gree of anaplasia of the cells and in some instances invasion of lymphatic and blood vessels. In the diagnosis of carcinoma arising in an adenoma the irregularity of the glands and the anaplasia are of paramount importance since whatever invasion is present is likely to be limited to the stalk. It is well known that some carcinomas of the large intestine simulate the cell arrangement of an adenoma so closely that the diagnosis of a malignant tumor depends entirely on the invasion of the wall of the intestine. Obviously a carcinoma of this type cannot be identified in an adenoma unless there is evident invasion.

In determining the presence of a carcinoma arising in an adenoma in this series, the general criteria suggested by Swinton and Warren have been used. These criteria are the presence of at least two of the following three conditions: (1) anaplasia, (2) irregularity of architecture, and (3) invasion. The anaplasia is characterized by a variation in the size of the cells and nuclei, deep-staining nuclei with prominent nucleoli and the presence of mitotic figures. The irregularity of architecture is characterized by either extensive stratification of cells or by intraglandular budding or by both. In all instances there is marked

variation in the polarity of the nuclei. The intraglandular proliferation of cells produces glandlike structures and cell masses which are not separated by a limiting membrane. Invasion is recognized when no definite border is apparent between the epithelial cells and the surrounding stroma. Using these criteria as the basis for the determination of the presence of malignancy, all gradations from adenoma with foci of carcinoma to unquestionable carcinoma could be demonstrated (Figs 1, 2, 3, 4, 5, 6, 7, 8, 9, 10).

A factor of primary importance in the histologic diagnosis is the site involved in the transition from adenoma to carcinoma. Some authors believe that the site of transition from adenoma to carcinoma appears first at the tip of the adenoma and others believe it occurs first at the base. In the present study no definite pattern could be established for the occurrence of the foci of carcinoma. In several instances the malignant change occurred at the periphery of the adenoma either at the tip or at the margins. In other specimens the transition occurred deep within the tumor near the stalk and at the base. With this fact established, it is obvious that an accurate

histologic diagnosis demands that an adequate number of sections be observed. The precision of the diagnosis will be proportionate to the care taken in the selection of representative sections. In a few adenomas the gross appearance of a firm solid gray focus was later confirmed histologically as a focus of carcinoma. Otherwise, there were no macroscopic identifying features of the malignant foci.

The smallest adenoma showing malignant change in this series measured 7 by 6 by 3 millimeters, and the largest, 9 centimeters in the greatest diameter. The median of the largest diameter of the tumors was 1.8 centimeters. Saint did not observe malignant change in any adenoma which was smaller than a walnut. In the present series several of the benign adenomas were larger than some of the adenomas with malignant foci. However, the adenomas with malignant foci as a group were larger than the class of benign adenomas.

The median of the largest diameter of the tumors was 1.8 centimeters. Saint did not observe malignant change in any adenoma which was smaller than a walnut. In the present series several of the benign adenomas were larger than some of the adenomas with malignant foci. However the adenomas with malignant foci as a group were larger than the class of benign adenomas.

When the incidence of adenomas and carcinomas in the negro race is contrasted with

the incidence in the white race a distinct difference is noted. As previously mentioned only 2.7 per cent of 181 negro patients showed adenomas of the large intestine in contrast with an incidence of 10.5 per cent in the white race. If only those patients over 30 years of age are considered then the contrast of the 3 per cent incidence in the negro race with the 16 per cent incidence in the white race is even greater. Furthermore, in this series of 181 negroes there was not a single instance of carcinoma of the large intestine. Karsner and Clark have analyzed the racial incidence in Cleveland of carcinoma of the large intestine. These authors state that Cleveland is a city with a large negro population, but in only 2 of 100 of their cases in which a note as to color was made was the patient a negro. Thus the data on racial incidence would indicate that both adenomas and carcinomas of the large intestine are uncommon in negroes.

Table V gives by age the incidence of (1) adenomas, (2) adenomas with foci of carcinoma, and (3) manifest carcinomas in the 1,279 white patients in the series covered by the present report. There were 134 patients with adenoma, 10 with adenoma with foci of carcinoma, and 25 with manifest or obvious carcinoma. From the figures in the table it is evident that in each of the three groups there is a greater incidence in the latter decades of the life span.

Among the entire group of 1,460 patients, both white and negro there were 139 large intestines containing adenomas. Of these 139 intestines having adenomas, 10 or 7.2 per cent contained one or more adenomas with malignant transition. In 8 of the 10 intestines the transition to carcinoma occurred in only a single adenoma. In the other 2 intestines, carcinomatous change was present in 2 and 3 adenomas, respectively. Furthermore, 2 of the 10 intestines containing a single adenoma with carcinomatous transition and the one intestine with triple tumors of this type also contained an obvious or manifest carcinoma. When the adenomas with malignant transition and the obvious carcinomas are classed together 4 of the 10 intestines each contained 2 or more malignant tumors. The occurrence of multiple primary malignant tumors has

TABLE V — AGE AND INCIDENCE OF CARCINOMA

been reported by Warren and Gates and by Brindley. The findings in the present study agree with the concept that the presence of one malignant tumor does not protect against the occurrence of a second malignant tumor and that a patient with a carcinoma is more likely to have a second carcinoma develop than the patient who is free from malignancy.

No informative data are gained from a morphologic study of the 25 examples of manifest carcinoma. In most instances the widespread growth of the tumor had destroyed the initial architecture making it impossible to identify pre-existing adenomas. Swinton and Warren were able to demonstrate that 14 per cent of the carcinomas of the colon arose in benign mucosal polyps and believed the percentage to be much higher.

In the 25 large intestines containing a manifest carcinoma, observed in the present series, there were associated adenomas in 13 instances. In the 10 large intestines containing an adenoma with carcinomatous transition there were associated adenomas in 8 instances. A comparison of the 25 cases of manifest carcinoma with the 10 cases of adenoma with carcinomatous transition shows that both groups were associated with additional adenomas in over 50 per cent of the cases. This common association is denied by Saint, who

HELWIG EVOLUTION OF ADENOMAS OF LARGE INTESTINE

47

stated that the two conditions are not frequently found in the same intestine. However, the figures in the present study lend support to the concept of an intimate association between adenomas and carcinomas.

TABLE VI — SITE AND INCIDENCE OF CARCINOMA

Site	Manifest Carcinoma	Carcinoma arising in adenoma	Carcinoma arising directly from mucosa
Cecum	3

Transverse colon	1		
Splenic flexure			1
Descending colon	10	7	1
Sigmoid colon	6	3	
Rectum			

Another important factor is the correlation between the distribution of the manifest or unquestioned carcinomas and the adenomas with carcinomatous transition. In this paper tumors which occurred within 15 centimeters of the mucocutaneous junction of the anus are designated as rectal. As would be expected difficulty was encountered in determining exactly the site of carcinomas situated at the junction of two segments. If over 50 per cent of a tumor was located in a given segment it was then assigned to that segment. The inability to identify correctly the segment in which the tumor is located probably explains the variation in the distribution of carcinomas of the large intestine as recorded in the literature. It was previously shown that the sigmoid colon is the most common site of benign adenomas. From Table VI it is evident that the sigmoid colon is also the most common site of adenomas with carcinomatous transition and of the manifest carcinomas. Likewise benign adenomas adenomas with malignant transition and manifest carcinomas frequently involve the rectum, cecum and ascending colon and less frequently the flexures, transverse colon and descending colon. Thus the distribution of the tumors is another line of evidence of the intimate relationship between adenomas and carcinomas.

The incidence of adenomas is slightly more common in men than in women. In the group of 25 patients with manifest carcinoma 15 were men and 10 were women. Of the 10 patients with adenomas showing foci of carcinoma 7 were men and 3 women. Since the ratio of men to women in the entire series of patients was 17:1 there were no significant sex differences in the three groups.

CARCINOMA ARISING DIRECTLY FROM THE MUCOUS MEMBRANE

Although there is much evidence that many carcinomas of the large intestine develop in previously existing adenomas, some carcinomas undoubtedly arise directly from the

mucosa. In the present study two small or histologic carcinomas without morphologic evidence of a pre-existing adenoma were encountered. These small carcinomas contribute informative material for study which cannot be gained from carcinomas in the advanced state. Both of the tumors occurred in men. One of the carcinomas was located in the distal part of the descending colon and the other occurred in the distal part of the sigmoid colon. In neither instance were adenomas present anywhere in the large intestine. The smaller of the two tumors located in the sigmoid colon appeared as a moderately firm gray sessile elevation with a slightly depressed center. The diameters of the tumor were 6 by 3 millimeters and the height, 2 millimeters. The larger tumor was situated in the descending colon. It appeared as a firm gray sessile elevation with a slightly irregular surface. The diameters of the tumor were 11 by 13 millimeters. The periphery of the tumor was elevated up to 2 millimeters in height and the central area was slightly depressed. A transverse section of this tumor revealed gray streaks extending into the underlying submucosa and muscularis.

The microscopic characteristics of these tumors are illustrated in Figures 11, 12, 13 and 14. A small segment of the mucous membrane contains a number of abnormal glands. However not all of the glands within the given segment are altered. Thus, one or several abnormal glands are interspersed among essentially normal ones. The outstanding feature of the abnormal glands is the change in the character of the lining cells. This change may involve all of the cells lining a gland or only a few of them. The definition between the normal cells and the abnormal is occasionally abrupt. The altered cells are enlarged

SURGERY GYNECOLOGY AND OBSTETRICS

TABLE V—AGE AND INCIDENCE OF CARCINOMA

the incidence in the white race a distinct difference is noted. As previously mentioned only 2.7 per cent of 181 negro patients showed adenomas of the large intestine in contrast with an incidence of 10.5 per cent in the white race. If only those patients over 30 years of age are considered then the contrast of the 3 per cent incidence in the negro race with the 16 per cent incidence in the white race is even greater. Furthermore in this series of 181 negroes there was not a single instance of carcinoma of the large intestine. Karner and Clark have analyzed the racial incidence in Cleveland of carcinoma of the large intestine. These authors state that Cleveland is a city with a large negro population but in only 2 of 100 of their cases in which a note as to color was made was the patient a negro. Thus the data on racial incidence would indicate that both adenomas and carcinomas of the large intestine are uncommon in negroes.

Table V gives by age the incidence of (1) adenomas (2) adenomas with foci of carcinoma and (3) manifest carcinomas in the 1,279 white patients in the series covered by the present report. There were 134 patients with adenoma, 10 with adenoma with foci of carcinoma, and 25 with manifest or obvious carcinoma. From the figures in the table it is evident that in each of the three groups there is a greater incidence in the latter decades of the life span.

Among the entire group of 1,460 patients, both white and negro, there were 139 large intestines containing adenomas. Of these 139 intestines having adenomas, 10 or 7.2 per cent contained one or more adenomas with malignant transition. In 8 of the 10 intestines the single adenoma occurred in only a carcinomatous change was present in 2 and 3 adenomas, respectively. Furthermore 2 of the 10 intestines containing a single adenoma with carcinomatous transition and the one contained 20 obvious or manifest carcinoma. When the adenomas with malignant transition and the obvious carcinomas are classed together 4 of the 10 intestines each contained 2 or more malignant tumors. The occurrence of multiple primary malignant tumors has

been reported by Warren and Gates and by Brindley. The findings in the present study agree with the concept that the presence of one malignant tumor does not protect against the occurrence of a second malignant tumor and that a patient with a carcinoma is more likely to have a second carcinoma develop than the patient who is free from malignancy.

No informative data are gained from a morphologic study of the 25 examples of manifest carcinoma. In most instances the widespread growth of the tumor had destroyed the initial architecture making it impossible to identify pre-existing adenomas. Swinton and Warren were able to demonstrate that 14 per cent of the carcinomas of the colon arose in benign mucosal polyps and believed the percentage to be much higher.

In the 25 large intestines containing a manifest carcinoma, observed in the present series, there were associated adenomas in 13 instances. CARCINOMA ARISING DIRECTLY FROM THE MUCOUS MEMBRANE

Although there is much evidence that many carcinomas of the large intestine develop in previously existing adenomas some carcinomas undoubtedly arise directly from the

mucosa. In the present study two small or histologic carcinomas without morphologic evidence of a pre-existing adenoma were encountered. These small carcinomas contribute informative material for study which cannot be gained from carcinomas in the advanced state. Both of the tumors occurred in men. One of the carcinomas was located in the distal part of the descending colon and the other occurred in the distal part of the sigmoid colon. In neither instance were adenomas present anywhere in the large intestine. The smaller of the two tumors located in the sigmoid colon appeared as a moderately firm gray sessile elevation with a slightly depressed center. The diameters of the tumor were 6 by 5 millimeters and the height, 2 millimeters. The larger tumor was situated in the descending colon. It appeared as a firm gray sessile elevation with a slightly irregular surface. The diameters of the tumor were 11 by 13 millimeters. The periphery of the tumor was elevated up to 2 millimeters in height and the central area was slightly depressed. A transverse section of this tumor revealed gray streaks extending into the underlying submucosa and muscularis.

The microscopic characteristics of these tumors are illustrated in Figures 11, 12, 13 and 14. A small segment of the mucous membrane contains a number of abnormal glands. However not all of the glands within the given segment are altered. Thus, one or several abnormal glands are interspersed among essentially normal ones. The outstanding feature of the abnormal glands is the change in the character of the lining cells. This change may involve all of the cells lining a gland or only a few of them. The definition between the normal cells and the abnormal is occasionally abrupt. The altered cells are enlarged

but not uniformly so and the cytoplasm stains intensely. The nuclei generally exhibit an appreciably greater enlargement than do the cells and are distinctly hyperchromatic. The nucleoli are likely to be enlarged and prominent. A survey of several cells shows a conspicuous variation of the nuclear polarity which contrasts sharply with the basal arrangement of the nuclei of the normal cells. A number of mitotic figures are noted. However the presence of mitotic figures is of questionable significance because mitosis is a common occurrence in normal mucosa. Not uncommonly there is true stratification of the abnormal epithelial cells and occasionally intraglandular budding. In the smaller tumor the atypical glands extend downward to interrupt the muscularis mucosae. In the larger tumor the invasion is much more evident. The atypical glands have infiltrated the submucosa and extend through the muscularis into the subserosal fat. A lymph node in the subjacent fat is free from tumor. However the submucosal veins and lymphatics not only beneath the tumor but also beneath the contiguous normal mucous membrane are filled with neoplastic cells. In the smaller tumor there is a slight increase in the amount of the submucosal connective tissue which is relatively dense. The larger tumor shows a much greater increase in the amount of connective tissue and the density varies in different fields. In most fields where the tumor has infiltrated the desmoplastic quality of the tumor is demonstrated. Both of these tumors have in common many abnormal histologic and cytologic changes. In the smaller tumor the degree of invasion is slight but in the larger tumor it is unquestionable. It seems logical therefore, in view of the common cytologic and histologic alterations, to regard both tumors as carcinomas. Moreover it seems fair to consider the incipient invasion present in the smaller tumor as the initial stage in the development of unquestioned invasion. In neither carcinoma was it possible to demonstrate the structure of an adenoma. It is conceivable that a pedunculated adenoma with malignant transition existed at one time and subsequently became torn from its attachment to the colon by peristaltic action.

However in the absence of such proof it seems reasonable to conclude that these two carcinomas arose directly from the mucosa and not through the evolution of an adenoma.

In brief then small or histologic carcinomas of the large intestine occurred in 12 of the 1,460 patients in this series. On the basis of the evolution of these carcinomas, the patients can be divided into two groups.

In the first group are those patients in whom the carcinoma developed in an adenoma. There were 10 patients with tumors of this type. In 8 of these 10 the large intestine contained a single tumor, one intestine contained two tumors and another three tumors. Three of the 10 large intestines with carcinoma present in an adenoma also showed an obvious or manifest carcinoma, and all but 2 contained benign adenomas elsewhere in the large intestine.

In the second group are those patients in whom the carcinoma developed direct from the mucosa and not in an adenoma. There were 2 patients with tumors of this type. In both instances the carcinomas were single lesions and in neither instance were there adenomas or carcinomas elsewhere in the large intestine.

When both groups are considered together 4 of the 12 large intestines presented solitary tumors. In 2 cases the tumor was a carcinoma arising in an adenoma and in 2 a carcinoma arising direct from the mucous membrane. The large intestine of each of the remaining 8 patients contained at least one instance of a carcinoma arising in an adenoma and in addition either benign adenomas, a manifest carcinoma or both. In the study of 25 patients with manifest carcinoma in this series, there were either benign adenomas or adenomas with malignant transition present elsewhere in the large intestine in 13 instances. In the other 12 intestines a carcinoma was the only tumor present. Thus, both in the group of histologic carcinomas and in the group of manifest carcinomas there were other tumors of glandular origin present in over 50 per cent. The group of 12 small or histologic carcinomas does not constitute a large number of cases. Of the 12 patients, the carcinomas in 10 arose in an adenoma and in the other 2 arose direct

from the mucous membrane. If this small group is representative of the evolution of carcinoma of the large intestine in general then the majority of carcinomas of the large intestine develop in adenomas.

SUMMARY AND CONCLUSIONS

1 Adenomas of the large intestine are true neoplasms and not a reaction consequent to a diffuse inflammatory process.

2 The incidence of adenomas of the large intestine increases with age. An appreciable increase in the incidence begins in the fourth decade and reaches a maximum (24 per cent) in the eighth decade.

3 Adenomas are more common in the white race than in the negro race.

4 Adenomas are slightly more frequent in men than in women in all sites of the large intestine.

5 In the series here reported on 58 per cent of the patients with adenomas had single tumors. Single adenomas are more common in women (63 per cent) than in men (55 per cent).

6 Multiple adenomas are as common in the fourth decade as in the eighth decade of life in those patients who have adenomas.

7 Inflammation, hemorrhage and hemostasis are commonly observed in the larger adenomas.

8 The incidence and distribution of adenomas of the large intestine have been carefully determined in 1,460 consecutive autopsies. Histologic evidence and cytologic evidence have been presented to the effect that adenomas of the large intestine undergo malignant transition.

9 Collateral evidence of the intimate relation of adenomas to carcinomas of large intestine is cited. In this series both adenoma with malignant transition and manifest or unquestioned carcinoma are more common in the older age groups. Likewise, both adenoma with malignant transition and unquestioned carcinoma show similar sites of predilection in the large intestine.

10 Two carcinomas arising directly from the mucous membrane are described.

11 Some carcinomas of the large intestine arise directly from the mucous membrane but the majority develop in adenomas.

SURGICAL FUSION OF THE VERTEBRAL ARTICULAR FACETS TECHNIQUE AND INSTRUMENTS EMPLOYED

HENRY W MEYERDING M D F.A.C.S. Rochester Minnesota

COMPLTE bony fusion of the vertebral articular facets prevents motion of the spinal column. When these facets are fused by surgical methods and the added support of massive bone grafts is employed fixation of great strength results. In previous publications (1-3) I have illustrated the method I employed in producing adequate strength in the fused areas to withstand the stress and strain on the spinal column in action. In the past 3 years I have designed several new instruments (4) and improved the technique of fusion of the facets sufficiently to make it appear advisable to describe the method now employed. It has been obvious that there is considerable interest in this method and the results obtained from it.

In the past I have employed fusion of the intervertebral articular facets in addition to massive autogenous bone grafts with excellent results. It is now my belief that a thorough

From the Section on Orthopedic Surgery Mayo Clinic.

bony fusion of the intervertebral articular facets themselves may provide adequate fixation.

By far the greatest difficulty encountered in fusion of the facets results from inadequate exposure of the parts to be fused. In order that the surgeon may see the facets, the incision should be ample, the spinous processes and laminae thoroughly denuded, and the erector spinae muscles retracted laterally. Many retractors have a tendency to slip from the muscles and, if this occurs, it is impossible to gain access to the articular facet. Therefore, retractors of varying widths have been designed which are deep enough to reach into the depths of the wound easily; the retractor edges have short teeth bent toward the handle (Fig. 1). With such instruments it is possible to grasp the tissues, capsule, and muscle and retract them laterally well away from the lamina and maintain exposure of the facet.

It is not always easy to recognize the articular facets even when they are exposed prop-

Fig. 1. Newly designed laminectomy retractor demonstrating exposure of intervertebral articular facet. *b*, Retractor showing toothed edge. *c*, Interarticular facet exposed by retraction of the capsule and muscles, laterally.

erly, for the articular spaces are narrow and sometimes are placed well laterally. The joints may be demonstrated by moving the spinous processes of the vertebrae with a forceps, thus disclosing the gliding articular surfaces. When the joints have been identified a sharp chisel is used to scrape the laminae from the bases of the spinous processes outward; this scraping turns up small shavings of bone and destroys the capsules and the posterior portions of the intra articular facets. This first stage of the operation may be sufficient in many cases to produce fusion of the facets and it was the method which was formerly employed.

The facets are true articular surfaces and it is wise to destroy them to obtain thorough bony fusion of the joint. It is necessary to have a narrow instrument to accomplish this and I formerly used a small curette. I have designed and now use a narrow chisel or a specially made sawlike eroder. No matter what type of instrument is used the cutting end absolutely must be controlled lest there be injury to the nerve tissues.

I have found a narrow bladed chisel, $\frac{1}{8}$ inch by 10 inches (0.16 by 25.4 cm.) and strong enough to withstand the force required to enter the articular interspace (Fig 2a) of considerable value in eroding the articular surfaces. To erode the facets the chisel is dug into the joint interspace and the debris is forced forward and outward as illustrated in Figure 2b. Bone chips then can be forced downward into the eroded interspace as shown in Figure 2c.

Recently I designed a small curved toothed saw which can be used to erode the articular surfaces of the facets even more efficiently than can the chisel (Fig 3). The teeth are offset and the cutting edge is curved slightly. When the saw is turned slightly in the joint and is dragged toward the surgeon it is found that the erosion of a facet is accomplished in a few strokes (Fig 4). The instrument has a large enough handle so that it permits abso-

Fig 2 a Narrow chisel, 10 inches (25.4 cm.) long and $\frac{1}{8}$ inch (0.16 cm.) wide. b Chisel being used to destroy joint surfaces of vertebral articular facets. c Chisel forcing bone chips into the eroded interspace.

lute control of the cutting edge by the surgeon.

Erosion of the articular surfaces is carried out bilaterally throughout the part of the spinal column that is to be fused. The bone shavings which were turned from the laminae and cancellous bone from the tibia then are forced into and piled about the destroyed facets. When the muscles are allowed to relax they cover the region and tend to hold the fragments of bone in position and a mass of new bone forms. When the procedure which has just been described is carried out firm fusion results. When it is employed in addition to massive bone grafts, it materially aids in the success of producing fusion of great strength (Fig 5 left and right).

Fig 3 Bone saw facet eroder 10 inches (25.4 cm.) in length. Teeth are offset so as to cut a groove $\frac{1}{8}$ inch (0.16 cm.) in width.

REPORT OF CASES

CASE 1: A nurse, 40 years of age, came to the Mayo Clinic because of intermittent low back pain of about 20 years duration. Coughing, sneezing, lifting, and stooping aggravated the pain and left sciatic pain developed and persisted for 6 months. Because of the pain it became necessary for her to

give up nursing about 3½ years before admission and do clerical work. In the 4 months prior to her admission symptoms became more severe.

On examination the patient was found to be a well developed and well nourished woman with limitation of forward and lateral bending of the spinal column. The knee and ankle reflexes were normal. Roentgenologic examination disclosed narrowing of the fourth and fifth and lumbosacral interspaces with hypertrophic changes, some lumbar scoliosis and a slight defect due to spina bifida at the first sacral vertebra (Fig. 6). The history and examination suggested the possibility of protruded intervertebral disc. A spinogram showed slight posterior displacement of the air column opposite the fourth lumbar interspace consistent with protrusion of an intervertebral disc at this level. The consulting neurosurgeon and orthopedist conferred and decided to perform laminectomy to explore the fourth and fifth lumbar interspaces for a possible protrusion of the intervertebral discs and if necessary to fuse the third, fourth and fifth lumbar vertebrae and sacrum.

Operation was performed on July 30, 1945. Partial laminectomy and decompression of the cauda equina with bilateral resection of the fourth and fifth lumbar ligamenta flava were performed. The findings at the fifth lumbar interspace were not abnormal. At the fourth lumbar interspace the ligament was abnormally thickened and the nerve root was more hyperirritable on the left side than on the right. The partial laminectomy thoroughly unroofed the hyperirritable nerve roots. A distinct ridge of bone extended across the fourth interspace but the intervertebral disc was not protruded. Then the spinous processes and laminae of the third, fourth, and fifth lumbar vertebrae and upper two segments of the sacrum were scarified. Bilateral fusion of the interarticular facets was performed and bone grafts were inserted on each side. Bone chips and cancellous

lumbar vertebrae. Grafts extend down onto the upper segments of the sacrum, bridging the spina bifida occulta of the fifth lumbar and first sacral vertebrae. The facets have been fused as shown in this roentgenogram.

Fig. 11 Case 2: Lateral view 5½ months after operation showing the spondylolisthesis of the fifth lumbar vertebra on the sacrum. The bone graft covers third, fourth and fifth lumbar vertebrae and upper half of sacrum.

bone obtained from the tibia were packed at the ends and under the grafts to make better contact.

Convalescence was uneventful and the patient was dismissed from the hospital on the thirtieth postoperative day at which time she was wearing a lumbosacral corset. She returned to her home physician for further observation.

The patient returned to the Clinic 8 months after operation. She stated that she felt better than at any time in the past 20 years. She had gained 8 pounds (3.6 kgm.) and had no backache. Roentgenograms showed that firm fusion of the bone grafts and fusion of the articular facets had occurred (Figs. 7 and 8).

CASE 2. The patient registered at the Mayo Clinic for the first time in 1940 when appendectomy was performed. He complained of backache and pain in the right hip of 2 years' duration and a diagnosis of spondylolisthesis was made at that time.

The patient was seen again at the Clinic in June, 1945, and in spite of the use of a lumbosacral support and other conservative treatment he still complained of backache and of pain in the left hip. These symptoms were aggravated by standing and the pain was projected to the calf of the left leg. It was suspected that possibly a protruded intervertebral disc complicated spondylolisthesis (2). Roentgenograms disclosed spondylolisthesis grade 2 (on a grading basis of 1 to 4 in which 1 represents the mildest and 4 the

most severe form) of the fifth lumbar vertebra on the sacrum, separation of the neural arch and a large spina bifida occulta involving the fifth lumbar vertebra and the sacrum (Fig. 9). Following neurologic and orthopedic consultation a combined operation was recommended. The neurologic surgeon explored the fourth and fifth lumbar interspaces after left laminectomy. Nothing abnormal was observed. Bone grafts were inserted on each side to include the third, fourth and fifth lumbar vertebrae and sacrum, the facets of the third, fourth and lumbosacral vertebrae were fused and multiple bone chips were inserted about the grafts.

The patient left the hospital on the twenty-eighth postoperative day. At that time he was able to walk, and the wounds were healed and in good condition. This patient was seen 5½ months later when he drove his automobile from his home community to Rochester for physical examination. Roentgenograms showed that the bone grafts were firmly fused (Figs. 10 and 11) and the facets were fused. He was advised to return gradually to further activity.

AXILLARY APPROACH TO SCHEDE THORACOPLASTY

ADRIAN LAMBERT M D F.A.C.S New York, New York

IN the treatment of chronic empyema Schede thoracoplasty has been utilized for those infections in which the visceral pleura has failed to re-expand sufficiently to approximate the parietal pleura and in which the parietal pleura has been sufficiently rigid to prevent its approximation to visceral pleura. Schede thoracoplasty consists of mass excision of chest wall including thickened parietal pleura, ribs, rib beds, intercostal muscles, nerves, and vessels overlying the extent of the infected space to allow the fresh extrathoracic muscle tissues to fall in and obliterate the infected space.

As originally described by Schede and the earlier writers the posterior approach was advocated to visualize the ribs overlying the cavity. Through a paravertebral right angle or hockey stick incision the trapezius and rhomboid muscles were divided posteriorly and the incision continued laterally around the tip of the scapula and brought forward dividing the latissimus dorsi posteriorly. The scapula was then retracted anteriorly and the ribs, parietal pleura, and intercostal muscles resected posteriorly and as far forward as the space extended to unroof the cavity. Following this the scapula and extrathoracic muscles fell in to fill the space previously covered with parietal pleura.

Employment of the posterior approach for Schede thoracoplasty is accompanied by complications of wound healing and infection that become apparent in any experience with the operation. If the posterior wound which is exposed to infection is closed tight, any movement of the scapula will tend to reopen the wound or weaken the suture line to cause sinus formation with possible breakdown of the entire wound from the adjacent infection beneath. Similarly, the latissimus dorsi muscle, which must be divided and exposed to infection will as a result, atrophy below the incision and will form a much less healthy

muscle for muscle graft at a later date. If the entire wound is packed and not closed the scapula will remain as a movable bone separated from its muscular attachments posteriorly. Between this bone and the spine will remain a sinus or groove of infection which must heal before the space can be obliterated. Also the wound, as estimated by the exposed surface is sizable and healing will take a correspondingly long time.

Such complications have been largely eliminated since the axillary approach to Schede thoracoplasty has been employed. The incision is so placed that pectoralis major and latissimus dorsi muscles are both preserved without impairment of blood supply. After the vertical incision has been made in the midaxillary line, these muscles are retracted anteriorly and posteriorly on either side of the incision so that both anterior and posterior segments of ribs are easily reached. The chest wall to be removed is excised from below upward beginning at the diaphragm. If the empyema is a complete one, and proceeding toward the apex of the pleural cavity. The approach to the pleural space is direct with minimal damage to extrathoracic muscles which may be useful later for muscle implantation. The incision itself is smaller, and there is not the large residual wound that occurs when posterior paravertebral hockey stick approach is used. Motion of the scapula postoperatively has little tendency to open the wound nor does infection tend to burrow beneath the scapula to form sinuses that may develop in the posterior approach after the wound is sewed up. Drainage ideally is placed directly in the center of the wound in the midaxillary line and will be dependent for the space that is being unroofed.

When preliminary thoracotomy is necessary in chronic empyema it should be performed through the midaxillary line at the most dependent portion of the pleural space. If the empyema is complete drainage is made at the junction of the diaphragm with chest wall

From the Department of Surgery, Columbia University and Chest Surgical Division, Bellevue Hospital, New York City

Fig. Insert shows patient placed on the operating table with the arm elevated and suspended for an axillary approach to the chronic empyema. The tube has been removed from the lower thoracotomy opening which was placed at the most dependent site of the empyema cavity in the midaxillary line. The small opening above the thoracotomy opening represents almost the site of the previous empyema necessitatis. T-shaped incision for the first stage Schede thoracoplasty operation is made at the dotted line extending toward the extrapleural thoracoplasty scar posteriorly.

Main picture shows a T incision deepened to separate the pectoralis major from the latissimus dorsi muscles. The midaxillary line. The thoracotomy opening into the pleural space is shown extending through the plaque of regenerated ribs which has formed since previous extrapleural thoracoplasty.

Such drainage is so placed as to allow easy access to the pleural space at the time of Schede operation and to preserve musculature posteriorly. Thoracotomy is performed with removal of segments of two ribs underlying parietal pleura. Intercostal muscle and rib bed are excised to allow a large opening. Thus if delay in the Schede thoracoplasty occurs the thoracotomy opening will remain adequate in spite of the tendency of the chest wall to contract with closure of the opening. Removal of the rib bed minimizes regeneration of rib at thoracotomy

site and simplifies the initial step later in Schede procedure.

At a suitable date following Schede thoracoplasty is performed with the patient lying on the good side with the affected side up and arm abducted and elevated over the head. The arm is suspended by means of a bar over the patient's head which exposes the axilla and retracts the axillary vessels upward to allow easy access to the apex of pleural cavity.

A transverse incision is then made at the base of the pleural space to include the thorax

Fig. 2

Fig. 2. Beneath the thoracotomy opening the 10th rib has been resected as have the costal cartilages of the 9th, 8th, and 7th ribs anteriorly. Dotted line outlines the limits of the underlying pleural space that is to be unroofed at this stage operation. Note that the costal cartilages have been removed an inch beyond the extent of the pleural space to allow gradual falling in of the tissues adjacent to the pleural space.

Fig. 3. Dotted line outlines the plaque of regenerated ribs, parietal pleura, and intercostal muscles that is to be removed at first stage operation. This is best performed with double action rib cutter and blunt scissors. Sharp rake retractor or hook will control the tissue to be removed, which in some cases may be over 3 inches in thickness.

Fig. 4. Pleural plaque is divided anteriorly and posteriorly care being taken to clamp intercostal vessels posteriorly as they are encountered to avoid unnecessary hemorrhage. Anterior vessels usually do not bleed sufficiently to require hemostasis. Forming the base of the saucerized space are the diaphragm below the pericardial pleura anteriorly and collapsed lung covered by visceral pleura extending upward from the diaphragm. Note anteriorly the small edge of parietal pleura at the re-entrant angle of pericardium with chest wall which has been removed in Figure 5 to allow even approximation of tissues.

Fig. 5. The ribs beneath the opening into the pleural space are removed subperiosteally. These may lie horizontally in which case it may be necessary to remove only one rib. Usually however the ribs are situated more vertically so that segments of several must be removed to allow the tissues immediately beneath the thoracotomy opening to fall

Fig. 3

in gradually. With the finger in the drainage opening it is possible to outline exactly where the parietal pleura, intercostal muscles and

Fig. 4

Fig. 5. The berelled edge of parietal pleura is clearly demonstrated anteriorly and posteriorly. The remainder of the chest wall is left for the next stage of the operation. Packing placed in the pleural space walls off the freshly divided muscle planes and prevents extension of infection to newly exposed tissues. A few through-and-through stitches are sufficient to approximate the tissues and minimize the external wound surface.

rib beds are to be resected and to judge accordingly how far the ribs overlying solid tissue should also be removed.

A vertical arm is then extended upward in the midaxillary line toward the apex of the axilla. This is deepened down to the ribs underneath dividing serratus anterior fibers and the axillary tissues to separate the pectoralis major anteriorly from the latissimus dorsi posteriorly. The tissues on either side of the incision are then retracted to expose the underlying ribs without damage to the muscles. With the index finger in the drainage site the outline of the pleural cavity is again defined and small segments of ribs are removed anteriorly and posteriorly at the re-entrant angle of the parietal pleura beneath. After such segments are

resected the large piece of chest wall is then removed with the help of large blunt scissors extending upward as far as is feasible without change in the patient's condition. Care must be taken during this part of the procedure to clamp the intercostal vessels posteriorly as they are met. A straight Kocher clamp is best utilized for this purpose. If these are not applied until the tissue is removed the patient will have lost a considerable amount of blood, which can be avoided by immediate application of the clamps. Not only should the ribs be removed beyond the limits of the empyema space but the parietal pleura should be leveled so that no ledge of tissue remains to form a groove and prevent approximation of fresh tissues with underlying visceral pleura.

Fig. 6 The ease of approach is clearly shown in this picture. At the second stage operation the wound is reopened and the axillary arm of the incision extended upward toward the apex of the pleural space. Dotted line represents the tissue to be removed overlying collapsed lung. Pectoralis major and latissimus dorsi muscles have been preserved and are retracted on either side.

Fig. 7 Segments of ribs again are removed anteriorly beyond attachment of visceral pleura to chest wall. Bleeders are clamped and tied posteriorly as they are encountered. Overlying ledge of parietal pleura must be excised as failure to do this is frequent cause of persistence of residual space.

In cases in which an extrapleural thoracoplasty has been performed before starting the Schede procedure the regenerated ribs and rib beds overlying the pleural space will consist of a rarefied mass of bone that has become confluent to form an irregularly solid bony plaque. In the past the Schede operation used to be performed by an attempt first to remove the regenerated plaque from the underlying periosteum and parietal pleura which was followed, if necessary, by resection of the thickened pleura. As the pleura almost always had eventually to be removed and in order to avoid the formidable bleeding that is encountered in that procedure initial resection is now employed to excise the chest wall *en masse* without any attempt first being made to separate regenerated bones from parietal pleura.

As in the operation where extrapleural thoracoplasty has not been first employed the extent of the pleural space is estimated with the finger in the drainage site and ribs, pleura bony plaque and intercostal muscles are divided with the rib cutter and blunt scissors. Difficulty may be encountered in visualizing the tissues during this operation. The superficial chest wall muscles should therefore be separated by sharp dissection from their attachments to the regenerated ribs during which procedure almost no bleeding will be encountered. A sharp rake retractor may then be

hooked into the pleural mass which will control the tissue and allow the operator to visualize the intercostal bleeders as they are encountered. Again importance is laid on immediate clamping of these vessels as they will not stop bleeding on removal of adjacent bone.

As in any serious operation on a debilitated patient constant attention should be paid to the general condition of the patient during the operative procedure. In the Schede operation the best index of the patient's condition is the pulse. A sharp rise of pulse even without corresponding fall in blood pressure should suggest to the operator an early termination of the operation. The operation itself should never be performed without ample amounts of blood frequently as much as 1500 to 2500 cubic centimeters of blood being given at a single stage operation. A gradual rise of pulse during the operation indicates a pause in the operative procedure while more blood can be administered and the patient's condition improved. Occasionally a patient's pulse is rapid before the operation is begun. In such cases blood should be running into the patient's veins before any incision is made and provided the pulse remains elevated a very small amount of surgery should be attempted at that stage. Thus the operator is in constant touch with the anesthetist and can judge the amount of surgery to which the patient is to be subjected.

Fig. 8. Final stage of the procedure shows completed operation with parietal pleura, intercostal muscles, vessels, nerves, and ribs removed to roof the underlying infected pleural space. Beveling of parietal pleura is shown up to the apex for even approximation of tissues. Packing will be removed after tissue planes are walled off and allow extrathoracic tissues to fall in on the visceral pleura of collapsed lung and obliterate the empyema space.

It usually requires two operations before a complete removal of chest wall can be effected although as many as six or more have been performed in patients in extremely poor condition. Since the procedure has been staged, severe postoperative reactions have been minimized and mortality markedly diminished. In earlier cases when the blood pressure was used as an indicator of the amount of surgery that should be given a patient, the patient's condition seemed satisfactory on leaving the operating table but was soon followed by a state of deep shock from which it was difficult to arouse the patient.

Patients with chronic empyema of any standing are notably debilitated. Not only are they underweight, chronically ill and with a ten-

dency to be anemic, but also they show a lack of normal blood volume which may account in large part for their inability to stand surgery of any degree. Individual patients will differ in this regard however and without careful studies it is difficult to predict in advance the response an individual will show. The importance of bearing in mind the various factors that may influence the patient's condition cannot be overemphasized as the amount of surgery that is performed will always depend in large measure on how much the patient can stand.

Finally axillary approach is well adapted for quick closure when it is necessary to terminate the operation. In contrast with the axillary wound the posterior approach must be

sutured in layers in order to effect tight closure. This step requires more time and must be considered in estimating the amount of surgery that can be performed.

Three or four through and-through sutures will approximate the axillary wound at its upper limit. Gauze packing is placed next all freshly divided tissue planes to stimulate a reaction in the tissues and to prevent extension of the infection. This packing is brought out through the dependent part of the wound and can be removed on the fifth to the seventh days. At this time when the gauze is

removed the extrathoracic tissues will fall in and adhere to the collapsed visceral pleura beneath.

SUMMARY

1 The technique of Schede thoracoplasty using the axillary approach is described.

2 The advantages of this approach over the posterior paravertebral hockey stick incision are emphasized, notable among which are ease of approach and closure of wound, preservation of extrathoracic musculature, avoidance of infection and postoperative complications of wound healing.

A HEMORRHOIDECTOMY ELIMINATING THE USE OF THE CLAMP

V T YOUNG M.D., Washington District of Columbia

A SATISFACTORY hemorrhoidectomy must remove all the hemorrhoids and redundant tissues. With certain obvious reservations, any type of operation which achieves a desirable end result is adequate. Operations involving the use of the hemorrhoid clamp are suitable in some instances. However it is technically difficult or sometimes impossible to manipulate the clamp so as properly to cope with cases in which hemorrhoids and redundant mucosa must be resected high above the pectinate line. Some other types of hemorrhoidectomy designed to eliminate the hemorrhoidal clamp are not completely satisfactory because of failure to achieve proper fixation of the rectal mucosa, inadequate control of mucosal bleeding or the tendency of the ligature to slip.

Following is a description of an operation eliminating the hemorrhoidal clamp. Under sacrocaudal or low spinal anesthesia with the patient in the jack knife position the buttocks are retracted laterally and held by means of broad strips of adhesive tape fixed to the op-

erating table. Having thus obtained adequate exposure, appropriate preoperative preparation and draping are carried out. At this point 6 cubic centimeters of 1 per cent diathane solution is injected into the sphincter muscle for the purpose of controlling postoperative pain. Using the finger as a guide, a 1/2 inch 22 gauge needle is introduced into the posterior midline just outside the anal verge. Two cubic centimeters of the solution is injected into the muscle at this site. The needle is partially withdrawn and reinserted in a right anterolateral direction. Two cubic centimeters of the solution is placed in the lateral quadrant of the muscle on this side. In the same manner the needle is again partially withdrawn and the rest of the anesthetic is injected into the left lateral quadrant of the muscle. It is felt that the logical time for this procedure is preoperatively rather than postoperatively because the swelling which necessarily results from a rectal operation increases the possibility of abscess formation following injections in this region.

After careful dilatation retracting clamps are applied to the margins of the anus and these are drawn apart. The hemorrhoidal masses are now grasped and exposed. In this manner the hemorrhoids are demonstrated and the degree of deformity is evaluated (Fig 1). The skin adjacent to one of the hemorrhoidal masses is grasped by a straight hemostat which is pulled in the direction away from the anus and held by an assistant. A second hemostat is fastened to the skin just inside the first and upward traction is exerted on this by the operator. With the skin thus placed under moderate tension an elliptical incision is commenced on the skin between the two hemostats which includes hemorrhoid and redundant mucosa (Fig 2). The hemorrhoidal mass outlined by the incision is dissected free from the external sphincter muscle and underlying tissues from below upward. Dissection is fa-

Fig. Hemorrhoids exposed. Insert shows position used for operation.

Fig. 2. Beginning the dissection of the hemorrhoidal mass.

cultated by maintenance of tension on the hemostats and the use of curved dissecting scissors. When the dissection has been completed the hemorrhoidal mass remains attached by a relatively narrow pedicle of mucosa (Fig. 3)

A ligature of No. 1 plain catgut is fixed in the following manner. The dissected hemorrhoidal mass is drawn away so as to expose the upper extremity of the line of incision on the side of the operator. The mucosa above the apex of the incision is included by a mattress suture. The ligature is now brought through the base of the pedicle on the same side. Next the superficial fibers of the internal border of the external sphincter muscle are included. The ligature is brought back through the base of the pedicle on the opposite side. Now, the hemorrhoidal mass is drawn in the other direction so as to expose the upper extremity of the incision on the side away from the operator. A mattress suture is placed in the mucosa above the apex of the incision on this side which completes the ligature. The suture is tied securely and the hemorrhoidal mass distal to the tie is amputated. Each of the hemorrhoidal masses is dissected, ligated and cut in the manner described. All bleeding points in the denuded areas are caught and tied. The stumps are carefully checked for bleeding by exposing each with a Smith rectal speculum. A thin strip of vaseline gauze or rubber dam is

Fig. 3. Dissection complete.

inserted in the anus for drainage. A dressing consisting of a small piece of gauze is laid over the anus. This dressing will remain in place without the aid of adhesive strips or a T binder. No other postoperative dressing is required.

The postoperative care is relatively simple and uncomplicated. When sensation returns, continuous hot packs are applied locally and liberal doses of morphine or pantopon are given to control the pain. A regular diet is allowed on the day of operation. The drain is removed the day following operation. Hot

Fig. 4. Ligature fixed.

Fig. 5. Appearance at end of operation.

packs are now discontinued and warm sitz baths are commenced three times daily. After each bath the raw areas are carefully swabbed with a cotton applicator soaked in 15 per cent alcohol following which, a small piece of dry cotton is laid across the anus. No other dressing or appliance is required. The patient becomes fully ambulatory after the first day. No attempt is made to prevent early bowel movement; the patient is encouraged to move the bowels after the first day. Laxatives are not allowed but a low tap water enema is given on the third postoperative day if the bowels have not moved by that time and every 2 days thereafter until the patient has daily unaided evacuations. Under this treatment a regular bowel habit is soon developed regardless of a previous history of the promiscuous use of laxatives or chronic constipation. Digital dilations are unnecessary because the daily dilatation produced by a formed stool is quite ef-

fective and considerably more comfortable for the patient to endure.

This type of hemorrhoidectomy presents several advantages. It is technically simple and may be used successfully for practically all types of hemorrhoids encountered. The hemorrhoid clamp is entirely eliminated. All the hemorrhoids and redundant tissues can be removed even though it may be necessary to dissect high above the pectinate line. Because of the several points of fixation the mucosa has no tendency to slip out of the grasp of the ligature. Bleeding is adequately controlled and the mucosa is well gathered in and drawn down where it is securely fixed at about the level of the pectinate line. Comparatively little raw surface remains a fact which makes the tendency toward stricture formation negligible.

The author has used this type of operation in 800 cases with excellent results.

SURGICAL CORRECTION OF NASAL DEFORMITIES

LOUIS T BYARS M.D. F.A.C.S. St. Louis, Missouri

THE nose is the most prominent feature of the face. Real or fancied nasal deformities have a high priority in the consciousness of the owner as well as the observer and cause many patients to seek correction.

Most corrections of nasal appearance depend upon shifting the interrelationship of the component parts of the nose or changing their size and shape and a good understanding of the rôle of the anatomical parts in supplying the framework to the external nose is necessary before undertaking any such correction.

The upper third of the external nose is supported by the nasal bones and the adjacent frontal processes of the maxillae, in the middle third are the paired upper lateral cartilages, which are continuations of the nasal bones and like the nasal bones are fused with the septum in the midline (Figs. 1 and 2). Consequently both nasal bones and upper lateral cartilages in addition to forming the side wall of the nose have an important rôle in supporting the dorsum and forming a part of the profile line. Inferior to the upper lateral cartilages are the paired alar cartilages, comprising for the most part the skeletal framework of the tip. These alar cartilages are more or less free floating (Fig. 3). They are not intimately adherent to the upper lateral cartilages as the latter are to the nasal bones. Although they are adjacent to the septal cartilage they are not attached to it as are the upper laterals. Thus the alar cartilages and their continuation into the columella supply a framework which gives bulk and shape to the tip of the nose as well as height. However as supporting structures, they depend on relatively loose attachments to the upper lateral and septal cartilages through the medium of soft tissues (Fig. 2). This relationship must be remembered especially in dealing with problems in which septal support to the lower portion of the nose has been lost.

From the Department of Surgery, Division of Plastic Surgery
Washington University School of Medicine.

The cartilaginous septum is the ridgepole which gives height to the lower two-thirds of the nose, supplies support to the other cartilaginous structures and oftentimes causes a shifting from the midline of the external nose when it has been displaced by trauma (Figs. 17 and 18). The septum is the one structure most often deformed and the one interfering with the function of the internal nose.

The external nose is covered with skin and an areolar type of subcutaneous tissue. The quality of this soft tissue covering differs in the upper and lower portions. Over the nasal bones the skin is thin, the subcutaneous tissue is scant in amount. The glandular structures are not as well developed or active as in the lower portion. At the tip of the nose the skin is palpably thicker and less mobile. The sebaceous glands are more active. The actual thickness of the epithelial structures is greater as is the thickness of the subcutaneous tissue. This soft tissue of the tip varies considerably the extreme being reached in the rhinophyma where the epithelial structures may sometimes be three-eighths of an inch in thickness (Fig. 28). Even under normal circumstances or slightly abnormal circumstances of seboreic inflammation the tip of the nose may be quite fleshy so that its shape is not due to the delicate lines of the cartilaginous structures but to the overlying covering envelope (Fig. 8).

CORRECTION OF THE LARGE OR HUMP NOSE

In planning the correction the balance of the patient's features must be considered. A prominent nose may appear even more prominent because of a receding chin (Fig. 25). In one instance a nose may be shortened more than in another where a long lower jaw is present. The proper width, height, and length of the nose must be determined in proportion to the other features. It is common for a patient to insist that all that is wanted is the removal of a hump. In most instances, when one feature of a nose is corrected, other faults are im-

Fig. 2. Plaster cast of the face used in planning nasal correction. One-half of the nose is carved down to represent the desired change. The other half of the nose is left intact for contrast. This method is quite objective and promotes accuracy of correction.

mediately accentuated. All of the component parts must usually be altered and the preliminary planning is extremely important.

A number of rules or methods have been described for this. Some surgeons can do this free-hand, merely looking at the patient, studying the features, and making the decision without mechanical aid. It is felt that a more objective method is desirable. In every case a plaster cast is made of the face and on

this cast the correction is worked out, carving down the lateral half of the nose to represent the alteration planned and leaving the other half for comparison (Fig. 1). By this method, the surgeon may fix in his own mind what he wants to do. The patient may also see what is being planned and more accurately describe his own ideas. Moreover, having this cast at the operation enables the surgeon to make excision of bone or cartilage by fairly accurate measurement. It is easy to get lost on the individual patient if the correction is being done free hand.

Most nasoplasties involve certain standard corrections, the chief difference from one nose to the next being in the amount of excision at varying points. The more or less standard correction consists of lowering the profile line or removing a hump (Fig. 3). This results in a plateau on the top of the nose rather than a thin dorsum (Fig. 4). For this reason the nasal bones must then be narrowed, re-establishing the normally thin dimension. The tissue which is removed in correcting a hump or high profile line is the summit of the nasal bones, the portion of the upper lateral cartilages fused with the septum, which constitutes part of the width as well as the height of this hump, and a portion of the septum contribut

Fig. 3. a, left, The initial incision is between upper lateral and alar cartilages. The knife passes over the upper lateral cartilage and dorsum of the nose, separating all soft tissue from the cartilage and other structures constituting the hump. b, Having made the incisions in both nostrils, they are then extended medially to separate the columella from the lower border of the septum. These initial incisions do not cut cartilage but separate one cartilaginous structure from another.

Fig. 3. After elevation of the soft tissues from the dorsum of the nose, the hump is removed with the Joseph saw. The amount of excision is estimated from study of the cast, which is present at operation. Note that the hump consists of bone, upper lateral cartilage and nasal septum.

Fig. 7. Correction of pendulous columella requires excision of some of the columellar cartilage. A full correction cannot be made by additional excision of septal cartilage. The excision represents removal of skin and inferior border of the hypertrophied cartilage.

also necessary to shorten the side walls so that the length will have been reduced asymmetrically. This is done by excising a triangle from the inferior borders of the upper lateral cartilages. These corrections varying in amount and degree constitute the typical nasoplasty. To meet specific problems other maneuvers may be added.

Fig. 8, above. Equally good results cannot be obtained in every case. The result of nasal correction depends upon the absorption of excess skin and the soft tissues adapting themselves properly to the newly shaped skeleton. If the skin of the nose is normally thin, it may be expected to reflect the changes in the skeleton of the nose very accurately. However, if the soft tissue covering is thick and hypertrophied, the final result will lack the delicate lines and configuration desired. This complication must be foreseen. In some cases, it is perhaps wiser not to do the operation. In others, the complication must be explained to the patient beforehand so that too much will not be expected. a, left, I. This case, tip of the nose is unusually high and the skin quite thick. Because of the magnitude of the desired reduction,

Hanging columella In some instances, hypertrophy of the columellar cartilage causes a down bulging termed "hanging columella." It is a mistake to try to correct this displacement by excising more of the inferior border of the septum and forcing the columella up to it. A certain improvement may be gained in this manner but the full correction will come from the excision of an ellipse of skin and columellar cartilage taken on either side of the columella just above its inferior border (Fig. 7). This ellipse is the length of the columella and varies in width, depending on the degree of the desired correction.

Secondary corrections Although in most instances full correction is gained at the first operation not infrequently small secondary corrections are desirable. There may be more relaxation of tissues and secondary drooping of the tip of the nose than are anticipated. This may produce a certain roundness of the profile just above the tip. Occasionally in dealing with large noses, the transverse distance between the base of the alae is too great. This may be narrowed at the primary operation. However, it is a small procedure and it

and because of the thickness of the skin, one would not expect a really good result following an operation. In some instances, further help may be gained by excision of a prism or section of the full thickness of the ala at its junction with the cheek. This was done in this case, and the result shown in b, right, is a decided improvement.

Fig. 9, above. a, left, Facial deformity of relatively common type. Note retrusion of middle portion of face. The tip of the nose is less prominent than the dorsum and is situated in a depressed area. The attachment of the ala to the cheek and the base of the columella are retruded. The columella forms an acute angle with the lip, and the lip forms too great an angle with the vertical profile line. b, Correction in one operation by technique in Figure 10.

Fig. 10. a. The initial incisions are described in Figure 2. The incision separating the columella from the lower border of the septum is continued deep enough to enter the upper labial sulcus. A transverse incision is made in the upper labial sulcus from the molar region on one side to a similar point on the opposite. The upper lateral cartilages are divided from the septum on either side. The upper lateral cartilages are then sutured together over the septum to fill in the slight depression above the tip. The alar cartilages are sutured forward in an advanced position on the lower border of the upper lateral cartilages as illustrated in b. The columella is sutured in a forward position on the lower septal border. The tissues of the lip and cheek are advanced toward the midline as shown in c, and sutured in such position as to build up a greater bulk of soft tissue under the base of the alae and columella, forming a tip of the nose which is now more prominent than the dorsum, and correcting a retruded position of the base of the alae and lip.

is felt that it can be most accurately done after the nose has recovered from the operation, and the proper final relationship of the base of the nostrils to the point of the tip can be ascertained. If too much narrowing of the base of the nostrils is done then the nose viewed from below is not triangular but more globular than normal.

The nose with a very fleshy tip does not lend itself well to correction. Here the shape is due more to the thickness of the skin than to the contour of the alar cartilage. In lesser degrees, this may be corrected by trimming subcutaneous tissue from between the alar cartilages and skin and removing the attached areolar tissue from the external surface of the upper lateral cartilages.

External excisions. In certain larger and grotesque noses it is necessary to make excisions of prisms of skin and subcutaneous tissue from the base of the alae at their attachments to the cheek (Fig. 8). This is not often

Fig. 11. Typical unilateral, complete cleft of lip and palate with the correction of the lip and nose that may be obtained at primary operation. This involves an incision between the upper and lower lateral cartilages with undermining of the alar cartilage, separating it from the skin of the nose. This wide undermining is usually done from the single incision between the upper and lower lateral cartilages. This permits shifting of the lining and covering of the ala in the process of re-establishing the floor of the nostril and curling the ala into its proper position. Often the correction cannot be made as good as it is ultimately desired. Moreover some increasing deformity may occur with growth.

Fig. 12. a, Deformity of nose secondary to cleft lip. Here inadequate primary repair was done and the deformity subsequent to the initial repair has increased. The nose is not in the midline and there is a decided slumping of the left alar border. b Shows correction obtained by shifting the nose to the midline, reoperating upon the lip, advancing the entire left ala, and repositioning alar cartilages as shown in Figure 17. c, Shows relative symmetry of the tip and a scar above the left nasal border representing removal of crescent of skin. Such an excision should never be made at the primary repair of the cleft lip.

necessary. In general where it is necessary the overall correction of the deformity will not give a result comparable to that obtained on less extreme cases.

Septal resection. The operator is often at a disadvantage if a septal resection has been performed prior to the nasoplasty. The removal of a hump could result in the disturbance of the remaining septal support of the dorsum. The adequate shortening of a drooping tip could necessitate the removal of the remaining inferior septal border with loss of tip support. If the septal resection is performed prior to the nasoplasty with the knowledge that the second operation is contemplated, these factors should be considered.

SNUBBED TIP AND RETRUSION OF THE MIDDLE THIRD OF THE FACE

Normally the tip of the nose is its most prominent portion. In certain cases the tip of the nose may be less prominent than the dorsum (Fig. 9). This does not refer to the loss of tip support following trauma or operation but to a congenital condition. In such cases the columella is short. The alae are set in a depression, the base of the upper lip is retruded, the upper lip rather than being more or less vertical protrudes so that its border is anterior to its base at the junction of the lip with the nose and columella. The correction of such a deformity entails the advancement of the entire tip of the nose and the upper lip, so that the soft tissues on which the tip of the

Fig. 13. Case similar to that illustrated in Figure 12, showing the rather extreme alar deformity which may occur subsequent to inadequate primary repair and which may also become more noticeable with growth and development of the nose. Repair was done by the scheme outlined in Figures 17 and 17.

Fig. 14. Illustrating the improvement in general facial appearance which may sometimes be gained by doing a complete nasoplasty at the time of correction of residual cleft lip deformity. The correction of the deformed tip of the nose involved reduction in size of the alar cartilages so that they were symmetrical in size and position.

nose rests have also been brought forward (Fig 10). The entire procedure must be made rather extreme because in the first few weeks following operation there will be a tendency for the tissues to settle and a portion of the correction will be lost.

NASAL ASYMMETRY ASSOCIATED WITH HARELIP

In the complete unilateral cleft lip the cleft extends through the floor of the nostril (Fig 11). The ala and alar cartilage on the affected side are pulled out into a straightened and distorted position. This can largely be corrected at the primary operation if it is done properly. However residual asymmetries are often present (Figs 12, 13, 14 and 15). In the partial unilateral cleft lip the cleft does not go through the floor of the nostril but there is

Fig. 15. The patient with deformity resulting from one single factor such as cleft lip may often be given a better overall result by correcting not only the primary fault, but other bad features as well. a, left. Illustrates deformity of upper lip and nose resulting from a cleft lip. Note also the prognathism. b. Illustrates the improvement which was gained by reoperating upon the lip and correcting the nose according to the technique illustrated in Figure 10. The prognathism was corrected by excising the lower border of the point of the mandible. The scar of the submental incision may be seen. The excised segment of bone is shown below.

attendant nasal deformity on this side. Provided good correction has been made at the original operation then the deformity present usually consists of a few definite distortions. The attachment of the ala to the cheek on the cleft side is often posterior to the normal (Fig 13). The alar cartilage on the cleft side is underdeveloped and smaller than its fellow causing a slumping of the alar border. The entire alar cartilage on the affected side has a more posterior position than its fellow. This is true also in its relationship to the upper lateral cartilage. The entire nose including the bony nose, may be deviated from the midline (Fig 21).

Often the operation may entail a complete nasoplasty and general reduction of size (Fig 14). If this is done, then by reducing the size of the normal alar cartilage the two may be more likely to compare favorably. Otherwise the adjustment must come in repositioning the alar cartilage on the affected side. One method of doing this is as follows. An incision is made between the alar and upper

Fig. 16. a, left, Large and unsightly nose, associated with breathing difficulties. The lower border of septum blocks the left nostril. The right nostril is blocked by the angle of deflection. In this case correction as obtained by doing a typical nasoplasty, reducing the nose in size and shortening it markedly. The amount of shortening permitted excision of a large triangle from the lower septal border allowing the excision of the entire obstructing portion. It is unusual to be able to shorten nose to this degree. However in many cases, part of the correction may be so gained. b, Shows the improvement in appearance and in airway. The hanging columella operation (Fig. 7) was also carried out on this patient. No septal resection was done.

lateral cartilages on the affected side with free undermining of soft tissues. The alar cartilage is then sutured forward to climb the upper lateral cartilage to a more advanced position. The alar cartilage is then mobilized as in the usual nasoplasty with the exception that its lateral portion is not divided from the columellar portion and is mobilized submucously. The columellar portion of this cartilage is sutured to overlie the dome of the normal cartilage (Fig. 27). This deprives the columella on the affected side of this columellar cartilage and adds the columellar portion to the alar cartilage which in itself is congenitally underdeveloped and small. A considerable improvement of the tip deformity may thus be obtained. If there is still some slumping of this alar border the excision of an ellipse of skin from above the alar border at the tip of the nose may raise (Fig. 13)

Fig. 7. a, left, Typical crooked nose resulting from childhood injury. A septal resection had previously been performed and patient's airway was adequate. b, Shows improvement which was gained by shifting the nasal bones to the midline and shortening the nose considerably. This permitted elimination of the supra tip depression. The lower lateral cartilages are advanced on the remnants of the upper lateral cartilages remaining after shortening the nose. The shortening of the upper lateral cartilages rendered them more stiff and stubby permitting better support to the nasal tip. The drooping due to partial loss of tip support in this case was corrected by substituting the support of the upper lateral cartilages for that normally supplied by the septum.

Fig. 18. a, left, Twisted nose resulting from childhood injury plus secondary loss of tip support and increasing drooping of the nasal tip following septal resection. b Shows correction obtained by shifting the bony nose to the midline, shortening the nose markedly, and gaining support by utilizing the remaining portion of upper lateral cartilages, as in Figure 17

the alar cartilages and the columellar cartilages. Secondary to this deficiency and distortion of the tissues, there is a developmental distortion resulting in malposition of such cartilage as is present. The complete correction frequently calls for multiple operations and a combination of procedures. First it is often necessary to advance the tip of the nose carrying with the columella an attached strip of tissue from the center of the upper lip thus lengthening the columella. Later, a bat wing or modified V type of incision can be made across the tip of the nose turning up the skin and underlying soft tissue and exposing the alar cartilages at the dome. These cartilages can then be sutured together in the midline to give a more pointed tip and the skin incision closed as a 'Y,' advancing the soft tissues to give a more prominent tip. Subsequent to this, the procedure as described under Snubbed Tip and Retrusion of the

Fig. 19. It is sometimes difficult to maintain a midline position of the lower septal border. If there is a resistance to the shifting of its position a more rigid method of holding it may be desirable. In such cases a silver wire may be passed around the mobilized spine over a small lead button. This wire can be attached to a tooth on the opposite side, anchoring the displaced septum in a position of overcorrection until healing occurs.

Middle Third of the Face may be carried out. With many cleft lips, associated with cleft palates, there is some underdevelopment of the maxilla. This underdevelopment of the maxilla may be associated with a relative or combined relative and actual overgrowth of the mandible giving an appearance of prognathism (Fig. 15). In order to get the best balance of the features and to shorten the lower third of the face to make it in proportion to the middle third an excision of bone from the mandible or the point of the chin may be done.

DEVIATIONS OF THE EXTERNAL NOSE FROM THE MIDLINE AS THE RESULT OF TRAUMA AND ASSOCIATED SEPTAL DEFORMITY

Everyone in infancy or later has had trauma to the nose. Even relatively slight trauma in early childhood with no deformity at that time may result in increasing external deformity of the nose with growth. The typical history of such a case is that of a mild injury at 5 or 6 years of age with slight deformity beginning at about 12 years of age and reaching a maximum at 16 or 17. In these cases the anterior view of the nose shows it to be somewhat of an S-shape the bony portion being deviated to one side the middle third curving to the opposite side and the tip usually deviating in the same direction as does the bony nose (Figs. 17 and 18). It is presumed that in

Fig. 9. a, left, Illustrating the extreme depression of bridge resulting from an abscess and loss of septum in childhood. Not only is there loss of septal support but a portion of the growth stimulus to the nose has been lost. This results in an overly short nose out of proportion to the length of the rest of the face. The soft tissue covering and lining of the nose is deficient. If allowed to persist through the growing period, correction becomes increasingly difficult because of the relative deficiency of soft tissues. b, Shows correction gained at the age of 5 years by the insertion of a section of maternal cartilage. Such a correction does not an earlier age. Ill and I growth and development of the soft tissues of the nose, permitting the removal of the original implant and insertion of a larger one in later years.

such instances injury occurring to the septum with displacement of its attachments and perhaps hemorrhage within tissues has resulted in an increasing deformity with growth

Fig. 12. a, left, Depression of entire dorsum of nose secondary to infection in childhood. In this case the infection occurred late in childhood, and there is less shortening of the nose than in Figure 9. However there is a deficiency of bone as a result of the lack of growth stimulus. In many such cases there is a widening of the nasal bones, necessitating their being narrowed prior to building up of the profile line. Correction here was done in two operations with the result shown in b. At first operation the nasal bones were narrowed, and the second, a right angle support of rib cartilage was inserted to build up the dorsum and correct the retruded position of the columella.

Fig. 13. a, left, Depression above tip resulting from abscess of the septum in adult life. Here, septal support is lost. There is no change in the shape of the nasal base since full growth had occurred prior to the infection. This is a shrinking of the soft tissues of the lower portion of the nose, secondary to the loss of supporting structures. b, Correction gained by insertion of triangular piece of rib cartilage. Such a nose can rarely be built to its original size because of the shrinking which has occurred in the soft tissues.

the external nose being carried into the deviated position by the increasing distortion of the septum. In addition any trauma in later life can cause deviation of the bony nose and of the septum. As before stated almost all corrections of the external nose are made with the technique of the typical nasoplasty as the underlying principle. This is varied to meet individual cases. Correction entails bringing the bony nose to the midline, providing adequate breathing space and straightening septal structures which are causing deviation of the lower or cartilaginous portion of the nose. This may be combined with removal of a hump or other corrections of displeasing lines of the external nose. The bony nose is brought to the midline by free mobilization of the nasal bones and shifting them according to the technique described under Nasoplasty. A removal of a certain amount of septum is usually necessary first to provide breathing space by the removal of obstructions and second to weaken the septum diminishing its resistance to straightening. The lower border of the septum often offers the greatest problem. Frequently there has been a dislocation of the septum from the vomer and the lower border may be turned almost at a right angle, one nostril being obstructed by the bend or

Fig. 23. Supratip depression as a result of trauma. Correction consisted of septal resection to restore breathing space, removal of a slight amount of the prominence of the nasal bones, shortening the nose, and building up the depression above the tip by suturing together of the upper lateral cartilages across the dorsum of the septum. No implant was done.

angle of deflection the other by the free lower margin projecting into the opposite nostril. The best correction of this condition can be obtained by shortening the nose and excising the portion of the septum which is deflected (Fig. 16). Naturally this cannot be done in many cases because often a nose cannot be shortened to this degree and preserve a good appearance. In most instances it will be necessary to straighten this lower portion of the septum so that it again is in the midline. This relieves obstruction, corrects the deviation of the tip of the nose and restores support of the septum to the tip of the nose. This involves freeing of the lower portion of the septum from the angle of deflection to the lower border so that it may be moved like the rudder of a boat. The submucous resection having been done if necessary, superior to the angle of deflection a chisel is driven along the floor of the nose, cutting free the base of the septum and vomer from the palate. If done adequately this will permit bringing the lower section of septum to the midline. If there is resistance to the shifting of the position or if it does not remain freely in the new position it may be held by wiring to a tooth on the opposite side (Fig. 19). The inferior border of the septum is set into the groove between the columellar cartilages. Following complete healing a limited secondary resection of this

Fig. 24. Loss of septum from infection. This case was identical in history with that illustrated in Figure 21. However correction was made by utilizing local tissues entirely as in Figure 23. Having had a high nose originally it was possible to remove some of the nasal hump, making the depression relatively less deep. The nose was shortened and the upper lateral cartilages sutured together to fill the supratip defect. In this case it was possible to shorten the nose somewhat, facilitating this technique. In the patient shown in Figure 21 the nose was already too short and it was desirable to add to its length, making it unsuitable for utilization of local tissues only.

inferior portion of the septum may be necessary.

DEPRESSED NOSE

As the result of trauma, infection or operation the profile line of the nose may be depressed in part or throughout. If such an injury occurs in childhood the resulting defect is twofold. First there is flattening as the result of the injury and second a failure of de-

Fig. 25. a, left, Illustrating necessity of considering all of the features when planning a correction. The prominence of the nose in this case is accentuated by the receding chin. b, Shows correction of receding chin by implantation of rib cartilage to supplement the point of the mandible, and subsequent nasoplasty to reduce the size of the nose and improve its shape.

Fig. 26. The postoperative care and dressing is almost as important as the operation itself in getting a good final result. In applying this, one should remember that the dressing should attempt to do everything that was accomplished in the operation. The shortening of the nose should be maintained by holding the skin of the nose upward with adhesive strapping. The reduction of the hump should be supported by transverse strapping of the upper portion of the nose with adhesive tape. The narrowing achieved at operation must be held by splinting the nose in a narrowed position. If there has been deviation of the nose from the midline, the dressing should attempt to correct this deviation. a, Shows the adhesive strapping of the nose and the application of two small felt or adhesive pads stuck on with collodion. By application of splint over these pads, correction or even overcorrection of existing deviations may be obtained. Such pads and counterpads are usually not ap-

plied at the original dressing, but are used at subsequent dressings as indicated. b, Shows a small nasal splint of adhesive covered aluminum applied over adhesive strapping. This splint may be bent easily with the fingers and shaped by trimming with bandage scissors. It adheres to the nose through the medium of flexible collodion. c, Shows a different pattern of splint made of same material. In this one the splint is not attached to the nose with collodion, but is held in place with adhesive strapping. This adhesive strapping permits holding the splint and soft tissues of the nose backward more tightly against the skeleton. This is not commonly used as the primary dressing, changing to the smaller splint for subsequent dressings. A 15 day period of splinting is adequate for the simple uncomplicated nasoplasty. Where corrections of deviations of the nose have been made the period of splinting may be for longer periods.

velopment of the external nose in proportion to the other features (Fig. 20) and the nose is often widened.

The correction of such a condition involves the transplantation of some solid substance to supplement the normal supporting structures and restore the proper profile line. The transplanted material may be one of several. An autotransplant of cartilage taken from the patient's ribs is perhaps the best. This material is rigid and yet may still be carved with the scalpel. It is a living transplant of the patient's own tissue that heals well in place and is not subject to absorption or extrusion. The disadvantages are that an incision into the chest is required to procure the cartilage and

after transplantation it sometimes has a tendency to curl so that the straight line obtained at operation is not maintained. Preserved cartilage at the present time is being used quite extensively, often with quite good results. Its disadvantages are that it is a foreign body, and although it usually heals in place with very little reaction it is sometimes

Fig. 27. a, left, Inferior view of deformity of alar cartilages frequently found associated with unilateral cleft lip. b, scheme utilizing columellar portion of underdeveloped alar cartilage on the cleft side to restore symmetry of nasal tip.

Fig. 28. a, left, Rhinophyma of many years' duration with associated basal cell carcinoma in limited area. b, Result from shaving down thickened skin to the basal layers and shortening nose as in typical nasoplasty. Area of malignancy excised with the cautery and allowed to heal spontaneously.

absorbed and does not tolerate infection at all well. It does not have the tendency to curl. Living bone is difficult to shape and to obtain does require operation on the patient. Ivory and synthetic materials have the advantage of being easy to obtain but are rather difficult to shape at the operating table. These also are foreign bodies and are not as well tolerated by the tissues as are some other materials. It must be remembered that any transplant to the nose may be somewhat movable so that the patient may shift it slightly from side to side over the underlying structures unless it rests solidly on periosteum of the underlying bones. If so placed it adheres tightly to the periosteum and is not movable. Any transplant should supplement the deficient structures. Usually the transplant will overlie the depressed nasal bones. Inferior to this point it will supplement the septum and upper lateral cartilages which are also depressed. A single dorsal implant may be all that is needed if this implant adheres solidly to the nasal bones and gives adequate tip support, acting as a cantilever. However oftentimes the backward pull of the tip is such that adequate support cannot be gotten from a single dorsal implant. Also it is often necessary or desirable to lengthen the nose, bringing the columella down into a lower position. In this case the most desirable implant is a right angle in shape (Figs. 20 and 22). This is not the hinged transplant described by Gillies, which we have found impractical but represents a right angled insert carved from a single piece of cartilage taken from the curve of the rib cartilage near where it articulates with the rib. This is inserted through a columella-splitting incision, the longer dorsal projection resting over the nasal bones and elevating the profile of the nose. The shorter right angled portion lies in the columella, forcing it downward into a more desirable position and elevating the nasal tip. This supplements the quadrilateral cartilage and supplies the support which it normally would provide. In certain instances, rather than using a right angled insert, two separate implants can be used, one in the dorsum and the other in the columella and these are attached with a silk suture at their junction. These implants are shaped at the operat-

ing table with the scalpel, the same scheme being followed if preserved cartilage is used.

Often rather severe trauma to a nose will not fracture the nasal bones at all but will depress the septum causing a depression inferior to the border of the nasal bones and above the tip (Fig. 23). Such a depression may be handled in one of several ways. Most satisfactorily some of the height of the nasal bones may be removed making the supra tip depression relatively less deep, the upper lateral cartilages can then be detached from their connection with the septum and sutured together over the dorsum of the septum to elevate a portion of the depression (Figs. 23 and 24). If the nose can be shortened this will then bring the tip or alar cartilages into a higher position encroaching on the neighborhood formerly occupied by the depression and helping to obscure it still further. Some operators prefer the transplantation of one or more thicknesses of ear cartilage for these small defects. Usually if the depression is so slight that it may be satisfactorily filled in with a thin implant of this type, it can be better corrected by superimposing normal nasal structures. Moreover it is often difficult to place small bits of cartilage accurately in such a defect, and after healing the result will not be entirely symmetrical, the implant not fitting accurately to the depression. If the defect cannot be hidden by superimposing normal nasal structures over it, then it is usually safer to use a larger implant of rib cartilage.

A deformity occasionally following septal resection is the loss of support, causing a drooping tip. This gives an effect of elongation of the nose, the tip being less high from the lip than the position it formerly occupied (Fig. 18). Correction may be made in one of two ways. Through a columella splitting incision a post of cartilage may be transplanted into the columella itself simulating the support originally given by the lower border of the septum. In other instances where appearance will permit, it is possible to shorten the nose especially the side walls rendering the upper lateral cartilages less long and therefore more stubby and stiff. This supporting stiffness of the upper lateral carti-

lages may then be transmitted to the tip of the nose by suturing the upper border of the lower lateral cartilages to the upper laterals, sub-

stituting the support of the upper lateral cartilages for the lost support of the septum (Figs. 17 and 18)

CARCINOMA OF THE VULVA

Results of Treatment and Effect of Special Factors on Results

FRANK R. SMITH M.D. F.A.C.S. and ROBERT S. POLLACK, M.D. New York, New York

CARCINOMA of the vulva represents only about 4 per cent¹ of all cancers of the female genital tract (4,5 8 13). Yet on account of the opportunity it offers for early diagnosis, and the obvious failure to take advantage of this opportunity evident in most cases it deserves increased emphasis out of proportion to its incidence. This is especially so in view of the fact that increased knowledge in the treatment and prevention (19) of this type of cancer has been established during the past 5 years knowledge which may reduce somewhat the high mortality rate of the condition. The bulk of these cancers and this includes the vestibular and periurethral lesions, are skin cancers but because of their presence and location in a relatively specialized organ which is bathed in rich lymphatic trunks, it becomes not alone a local problem but like breast cancer one in which equal consideration must be given to the possibility and location of metastases.

Over a period of many years, a more or less standardized method of treatment has been developed for most cases of vulvar carcinoma. It is our purpose to evaluate the method in use at the Memorial Hospital with a brief description of some of the clinical and pathologic features of this disease. That this form of cancer is relatively uncommon (19) is not questioned yet despite this fact the literature is replete with statistics of end results and methods of treatment (5 13 15 16 18) histologic forms (2 10 12 21) age incidence (6 14).

Dr. Pollack is trainee, National Cancer Institute. From the Gynecologic Service, Memorial Hospital for the Treatment of Cancer and Allied Diseases.

¹There were 4,444 patients seen at Memorial Hospital between 1936 and 1943 who had cancer of gynecologic organ, 3 of these had cancer of the vulva, or an incidence of 4.6 per cent.

prevention (19) and general clinical description (8). However since Welch and Nathanson's review of their material reporting on life expectancy and incidence of carcinoma of the genitourinary tract material to 1933 only there have been no recent survival figures on a fairly large series. We shall present survival times of all primary cases seen at Memorial Hospital through 1940 as well as survival figures for those patients in the various stages of the disease process. Certain prognostic differences according to location and histology as well as extent of disease were also investigated.

During the 20 year period between 1926 through 1945 there have been 244 cases of cancer of the vulva at Memorial Hospital. For the purpose of this report we have divided this number into 2 groups the primary cases, 167 or those patients who came here without any form of previous treatment and the secondary cases 77 those who had received treatment in the form of either x-ray radium, or surgery at another institution. The primary group forms the basis of this report a brief discussion of the secondary cases will be given at the end. Because 16 patients did not have a histologic diagnosis of cancer this number was dropped from our study leaving an over all total of 228 histologically proved cases.¹

ETIOLOGIC FACTORS

In our series, the youngest patient with a malignant epithelial tumor of the vulva was 27 the oldest 89. Nine patients, or 4.1 per cent, with carcinoma were below the age of 40. Although this is a relatively small percentage,

10 of the 6 patients (1.5 per cent) are free from cancer well over 5 years; the remainder all died before the fifth year. At death the clinical diagnosis was carcinoma, vulva primary

it serves to remind one that vulvar carcinoma occurs in younger women not infrequently. Shannon and Marting reported a case complicating pregnancy in a 26 year old woman and also reviewed from the literature 5 cases of carcinoma of the external genitalia associated with pregnancy. Its presence in children where it becomes an oddity, has been reported on by Hoge and Benn. Baldwin's youngest patient was a girl of 14 who had a primary carcinoma of the vagina. In the present series, one of the patients with a melanoma was 15. Thirty-eight and seven tenths per cent of the patients were between the ages of 60 and 69, 25.4 per cent between 50 and 59, 18.3 per cent were between 70 and 79 and 8.7 per cent were 40 to 49. Forty nine and five tenths per cent of the patients were married, 36.6 per cent were widowed and 13.6 per cent were single. Seventy five and six tenths per cent had one or more children. 24.4 per cent were nulliparous. The high percentage of widowed patients is undoubtedly due to the large number in the older age groups and seems of no related significance.

Eight patients had syphilis but we were not struck by any difference in their disease as compared with the nonluetic. There were 10 diabetics recorded and 1 patient had a positive Frei test. None of these illnesses seemed to play a part in the etiology of the condition unless the vulvar pruritus commonly present in the diabetic can be termed a predisposing factor.

SYMPTOMATOLOGY AND SIGNS

In 70.1 per cent of the patients the presence of the lesion itself was the chief reason for seeking medical care. Pruritus, pain and bleeding in that order were the most common symptoms. Only 30 patients complained of increased vaginal discharge but a relatively high number, 47, noticed urinary burning and frequency. Two patients had dyspareunia.

From our series the importance of pruritus as a cancerous and precancerous symptom is undeniable. Itching and burning about the vulva was present in 128 or 56.1 per cent of the patients. Associated with this number were 83 patients (36.4 per cent) who had leucoplakia. As pruritus is the cardinal symp-

tom of leucoplakia this is not surprising. Nevertheless, the presence of these two factors despite the absence of other signs warrants vigorous treatment in the form of excision rather than close observation and temporization. The relationship between leucoplakia as a precancerous lesion and true cancer of the vulva is too well known for conservative therapy to be the method of choice.

HISTOLOGY

The histologic forms present in our series were as follows: epidermoid carcinoma, 189; melanoma, 25; basal cell carcinoma, 9; adenocarcinoma—Bartholin's gland, 2; vulvar Paget's carcinoma, 1; dermatofibrosarcoma protuberans, 1. Blair Bell and Datnow state that malignant disease of the vulva occurs as squamous carcinoma in over 90 per cent of all cases. This statement is found to be closely approximated by our series in which 84.0 per cent of the patients had an epidermoid type of carcinoma. Almost two-thirds of these (63.3 per cent) were grade II lesions.

A surprisingly high number, 25 or 11.1 per cent of melanomas are present in our series. Taussig (17) found 3 in his series of 155 patients. Folsome reported that he had found only 3 cases of melanoma of the vulva in the files of the University Hospital in Ann Arbor, between 1901 and 1940 or an incidence of 1 case to each 125,000 pelvic examinations. Although this type of lesion in general is rare, it has been seen not infrequently at our institution, probably because we recommend excision of most pigmented tumors on and about the vulva.

Nine or 4.0 per cent of the lesions were basal cell carcinomas. Berman reported on 4 patients with this type of cancer seen in St. Louis between 1927 and 1941. Wilson describes 4 cases collected by him from a series of 32 patients with carcinoma of the vulva seen at the Duke Hospital, an incidence of 12.5 per cent. Goebel and Hamann reported an incidence of 14.7 per cent basal cell carcinomas in their group but they note that this percentage is higher than any other obtained in the 5 years previous to their report. Folsome notes that basal cell cancers of the vulva are relatively rare, there being 6 cases in his report.

Chart 1. Survival curves.

There were 2 patients in our series with adenocarcinoma of Bartholin gland origin.

Sarcoma of the vulva is rare. It may occur initially in the tissues of the vulva, or in the vulvar end of the round ligament or it may represent sarcomatous change of a previously situated vulvar tumor. Taussig (15) notes that Leonard found 22.5 per cent of fibromas and fibroleiomyomas of the vulva that showed sarcomatous change. However Lovelady and associates, in a report on 34 benign neoplasms of the vulva, noted no sarcomatous change in any of their tumors. Folsome reported 1 out of 9 such tumors showing change.

END-RESULTS AND EFFECT OF SPECIAL FACTORS ON RESULTS

The end results of the primary and secondary groups of histologically proved cases seen between 1926 through 1940 is given in Table I. We have used the customary form in use at Memorial Hospital for reporting end-results. It deals solely with the overall cure rates and includes all of the histological types mentioned above. Our absolute 5 year cure rate is 26.00 per cent.

TABLE I—CARCINOMA OF THE VULVA—5 YEAR CURE RATES

Total number of cases	Primary 100	Secondary 24	Total 124
Indeterminate cases Dead of other causes—no evidence of cancer	7		8
Lost track of—no evidence of cancer	3	3	6
Total number of indeterminate cases	10	4	14
Determinate cases Total number studied minus indeterminate cases	90		110
Failures Dead of cancer	6	20	26
Lost track of—cancer present (probably dead)			
Living—cancer present			
Total number of failures	6	20	26
Successes Without evidence of cancer 5 years after application for treatment	26	13	39
Net 5 year cure-rate Successes divided by determinate cases	28.88%	54.17%	26.4%
Absolute 5 year cure rate Successes divided by total number of cases	28.88%	54.17%	26.4%

Clinical classification. This figure being a summation of all our cases, represents only a small part of the problem. We were especially interested in proving the importance of various factors on end results. To determine the effect of extent of disease, the cases were divided into five classes: (1) Cases without involvement of inguinal nodes—(A) with no extension of disease beyond the primary site on clinical examination and (B) those in which the inguinal nodes were dissected or biopsy tissue examined and no cancer found on pathologic examination; (2) Cases with inguinal nodes involved but operable—(A) those in which inguinal nodes were probably involved or enlarged on clinical examination and (B) those in which inguinal nodes were dissected or biopsy tissue examined and found positive for cancer on pathologic examination; (3) Inoperable cases with inguinal nodes fixed or immobile, swollen leg.

The survival curves of the primary group of patients in these classifications are given in Chart 1. All patients were treated by one or a combination of accepted methods: x-ray, radium or surgery. The total number of pa-

tients charted was 96. As would be expected those patients in class 1B those whose inguinal nodes were negative on pathologic examination, showed the highest survival figures. The rapid fall in the curves of classes 2A and 2B emphasizes the markedly changed prognosis once the disease has extended beyond its primary site.

Results in relation to type of surgical treatment. Twenty-one patients had a vulvectomy alone (Table II)¹ with one postoperative death. Five of these patients had enlarged inguinal nodes at operation and only 2 of this number survived 5 years. The overall 5 year cure rate for the 21 patients was 47.6 per cent. A higher survival rate would naturally be expected in this group as the disease was presumably limited to its original site when operation was undertaken. The fact that over 50 per cent of these patients did not survive 5 years emphasizes the high incidence of metastases which are not clinically discernible and should influence the procedure followed in treating these lesions.

Of 7 patients who had wide local excisions of the vulvar lesions mainly because of general debility and old age only 3 or 42.8 per cent survived 5 years.

There were 19 patients who had a vulvectomy with bilateral groin dissections. In all cases, the groin dissections were done at intervals of about 10 days following the vulvectomy and included dissection of the superficial and deep inguinal nodes including the so called Cloquet or femoral canal node but did not include the removal of the nodes along the hypogastric and iliac chains. Ten patients in this group (Table II) had negative inguinal nodes on pathologic examination and 8 or 80 per cent of these survived 5 years. Nine patients (Table II) had positive inguinal nodes and only 2 or 22.2 per cent survived 5 years. In 1 of these 2 survivals however, the primary lesion on the vulva was a melanoma.

Four other patients had a vulvectomy followed by bilateral groin dissections of the Basset type done at intervals of about 10 days. Three of these were patients whose in-

TABLE II —RELATION OF SURGICAL TREATMENT TO END-RESULTS

Class	Vulvectomy		Vulvectomy and bilateral groin dissection			
	A and 2A(S)		B		B	
	N	Per cent	N	Per cent	N	Per cent

Alive at 5 years		47.6	8	80	22	

guinal and iliac nodes were positive for carcinoma and they died within 2 years. The remaining patient is without evidence of disease today well over 5 years but her nodes showed no evidence of cancer on histologic examination.

Six patients had a vulvectomy and a unilateral groin dissection of the more superficial type. Four of these whose nodes were positive died within 2 years. One whose nodes were negative died within 30 months. The sixth patient had a melanoma which did not metastasize to the inguinal nodes until 7 years after a vulvectomy was performed. She died 6 months following a unilateral groin dissection.

Since 1940 almost all of the groin dissections done at Memorial Hospital have been of the Basset type but it is still too early for definite end results to be drawn. No postoperative deaths were encountered following any of the groin dissections.

Effect of radiation therapy. The inadequacy of x ray and radium in treating either the primary or metastatic foci of this condition is well known (4, 7, 17, 18). Only 4 patients were given x ray therapy to the vulva alone. All died within 18 months but 2 of these were beyond cure at the onset of treatment. One had a node removed from the supraclavicular area which on pathologic examination was consistent with a vulva primary.

There were 8 patients who received radiation to the vulva and groins and of these only (25 per cent) have been well over 5 years. In each of these the primary lesion was believed to be limited to the vulva only.

Eighteen patients were treated by vulvectomy and then were given radiation in the form of x ray, radium element pack or radon

¹As given, majority of patients succumb within 5 years, this figure is also given.

seed implantation into the nodes. Only 1 (5.5 per cent) of this group survived 5 years and 1 died as a result of the radiation. Half of this group had enlarged nodes on original examination. The one successful case was in a patient whose nodes were deemed enlarged and suspicious of containing cancer.

Location and its effect on end results. The site of origin of the disease cannot always be made with great accuracy because of the continuity of the structures and because the growth shows extension in all directions. Nevertheless, we were able to determine the localization of the disease with a fair degree of accuracy in most cases. Of 221 cases tabulated 133 or 59.6 per cent, originated on the labia majora 47 or 21 per cent on the labia minora and vestibule 27 or 12.1 per cent, on the clitoris and 13 or 5.8 per cent on the posterior commissure and perineal body. There were 2 cases of Bartholin gland origin also 1 on the mons veneris and one of the urethral meatus.

Table III shows the survival percentages of the primary group when divided according to site of origin. It has been our impression (and others, 16) that lesions of the clitoris are more virulent than those situated elsewhere. Although the number of cases is small the figures substantiate this impression.

Histology and its effect on end results. In Table IV we have listed according to histologic type the 5 year cure rate of the primary group of cases. As would be expected the melanomas have the lowest number of survivals. One of the two 5 year survivals with this type of lesion died of disease at 7 years and although the other successful case had inguinal nodes positive for metastatic disease the outlook for most patients with this

type of histology is very poor. Because of this, we advocate removal of nearly all pigmented tumors in this region.

Of the 5 patients with basal cell carcinomas 2 did not survive 5 years. However 1 of these patients died of another cause entirely unrelated to her cancer. Basal cell cancers, as is known are of a less virulent nature and tend to recur rather than metastasize but because of the exceedingly dangerous character of any cancer in this region we feel that vulvectomy and not so called wide local excision is the method of choice. These cancers do metastasize although not of course with the frequency of an epidermoid lesion. In Wilson's report of basal cell carcinomas in his own patients and those collected from the literature, 36 per cent died before reaching the fifth year.

The prognosis of the low grade epidermoid tumors appears from our series, to be approximately the same and undoubtedly is due to the vigorous form of treatment given a relatively weak lesion. The figures are too small for comparison of the grade II lesions with those of a more anaplastic type. It is our clinical impression however that most tumors more differentiated than grade I have a fairly similar clinical course. There was 1 patient with dermatofibrosarcoma protuberans of the vulva who is alive and well over 5 years.

SECONDARY GROUP

The patients falling into this classification were followed separately and analyzed in an identical manner. Treatment of patients was the same throughout. In general the survival times for this group are similar to those of the primary this is especially so as regards overall 5 year cure rates (Table I). Of 16 patients in class 1A (lesion localized to the vulva clinical

ly) 7 or 43 7 per cent survived 5 years this is a somewhat higher figure than in the primary group. Of 9 patients whose nodes were "suspicious" or thought to be enlarged (class 2A) but not dissected, only 1 (11.1 per cent) patient survived 5 years.

Fifteen patients fell into class 2B (positive inguinal nodes) and of this number 3 or 20 per cent survived 5 years this, too, is slightly better than the other group. In 2 of these successful cases the groin dissection performed was unilateral. All of these dissections were of the superficial type. Four other patients had 2 bilateral but no patient survived more than 3½ years. Treatment with x ray and radium gave equally poor results. When analyzed as to location lesions on the clitoris and labia minora seemed most virulent but the number of patients involved is small. Histologic types likewise showed no variation from the primary group there was only 1 patient with basal cell carcinoma and she died of cancer in 3½ years. In comparing the two large groups the similarity of end results is evident. This is so despite the fact that the secondary cases received treatment elsewhere and were treated by us in what we may assume is a later stage of the disease. In some cases therefore it would seem that there is a favorable period in which the disease is amenable to therapy, but once beyond this point no treatment appears successful.

COMMENT

It is needless to point out the marked difference between the early low grade lesions and those which have become metastatic and invasive. After studying groups of patients it becomes apparent that those who have received more vigorous and prompt treatment do better. Vulvectomy with at least a bilateral superficial groin dissection should be done in all cases adequate for surgery. Firm basis for this is seen in the high percentage of survivals (80 per cent) in the group with negative nodes (1B) where this was done, and the relatively poor showing (47.6 per cent) of the group (1A) where only vulvectomies were done because the nodes were thought to be negative at the

Our experience with the Basset type of groin dissection is still too young for definite opinion. Empirically one is always justified in removing all areas to which the disease may spread but it is somewhat questionable if in this condition removal of cancerous iliac nodes changes the prognosis. In Taussig's (15 16 17 18) series this type of dissection was done in a large number of patients but only 48.4 per cent of his operative cases had nodes positive for carcinoma and we do not know whether the inguinal nodes alone or the inguinal and iliac nodes together were involved. If the former circumstance exists a groin dissection as done by us in the series just reviewed should remove all positive nodes in this region. It would not, of course, remove any more highly placed metastatic deposits removal of which theoretically at least may give a higher survival rate.

We have no way of telling from our series whether excision *en masse* (i.e. groins and vulva together) or in stages as practiced by us at present, is the procedure of choice. Certainly a high percentage of patients in this age group are not ideal surgical risks and a two or three stage procedure may be tolerated with less difficulty.

Because of the very malignant nature of melanomatous lesions of the vulva it seems that removal of all pigmented tumors in this area is the only safe course to follow. As it is impossible to tell when a neuronevus or pigmented mole will begin to show cancerous change its local excision before this eventuality removes the threat which is ever present.

SUMMARY

Two hundred and twenty-eight cases of cancer of the vulva were studied. The condition is most prevalent during the seventh decade over half the patients experienced pruritus, and more than 80 per cent of the lesions were of the epidermoid variety. The melanomas showed the lowest survival rate. One hundred cases form the basis for the report of 5 year cure rates. Best results were obtained when a vulvectomy and bilateral groin dissection without removal of the iliac nodes, was performed. When the disease extends to the inguinal lymph nodes the prog-

SURGERY GYNFCOLOGY AND OBSTETRICS

nosis is markedly altered. The overall absolute
5 year cure rate was 26.00 per cent

MEDULLARY NAILING OF FRACTURES OF THE LONG BONES

W. RUSSELL MacAUSLAND M.D. Boston Massachusetts

THE treatment of fractures of the long bones by means of medullary nailing was introduced by Kuentscher in 1940. During the war the procedure was used rather extensively in Germany, and there are numerous reports on the subject in German literature. Boehler (2) in 1944, after studying the histories of more than 500 patients and over 10,000 x-ray films published a book on medullary nailing. The treatment has also been discussed to some extent in South American literature and Jimeno-Vidal and Guttner reported on approximately 100 cases. No reports on the use of medullary nailing by surgeons in this country have yet appeared although a few foreign reports have been reviewed in our literature (3, 8, 9). The treatment has interesting possibilities and this preliminary report on an adaptation of the method in the treatment of 7 fractures is presented with a view to provoking discussion.

In principle the Kuentscher method consists of introducing a long metallic splint through the medulla of both fragments. The splints are constructed of V_2A_1 steel and are bilaminar and V-shaped in cross section. They are made in different sizes and lengths. The nail is introduced at a distance from the site of the fracture. Its upper end, which is perforated, remains outside the bone, permitting the removal of the nail after healing has been established.

In the cases reported herein, nails made of tantalum were used, which is a nonelectrolytic metal and free from the flaws in metals requiring casting. The technique consisted of first opening the site of fracture and cleaning the ends of the fragments. The nail was introduced into the proximal fragment then the fragments were approximated and the nail was directed into the wound and driven into

the medulla of the distal fragment. With increasing study of this method it has seemed that a nail with a slight curve would provide for greater leverage and better immobilization than would the straight nail.

Medullary nailing has several advantageous features. It ensures the prompt establishment of absolute immobilization. The adjacent joints, however, remain free, permitting motion to be started promptly. Because of the complete fixation, ambulation or use of the extremity is possible at a surprisingly early date. It is particularly impressive to see a patient with a fracture of the mid femur walking with the aid of crutches in less than 3 weeks after the reduction. No supportive apparatus or plaster cast is necessary. Patients with fractures of both bones of the lower leg can walk in less than 2 weeks. A patient with a fractured humerus has good use of the arm in less than 2 weeks. Such early motion obviates the sequelae of rigidity, circulatory disorders, and atrophy from disuse. Because of the complete immobilization, the patient is free from pain. When the patient is elderly, the advantages of early motion are obvious.

The indications for medullary nailing are still not well defined. During the war it was used in Germany in treating fresh fractures of the femur, tibia, humerus, elbow, radius, and clavicle, as well as in cases of pseudarthrosis, but there is still no authorization for such wide application of the procedure. Boehler (2) concluded from his intensive study that only a limited number of fractures are suitable for medullary splinting and that the best results are obtained in transverse and short oblique fractures above the middle of the femur. Boehler (2) recognized definite contraindications in fresh open fractures of the leg, in infected fractures, and in fractures in children. On the other hand, Ehalt used the method principally, and with success, in open fractures of the lower leg.

SURGERY GYNECOLOGY AND OBSTETRICS

Fig. 1 left. M. B. The original fracture with medial displacement of the distal fragment.
Fig. 1. M. B. Roentgenogram taken 9 weeks after medial medullary splinting.

Fig. 3 left. A. M. Roentgenogram showing comminuted fracture with displacement following unsuccessful attempt at open reduction with screw fixation.

Fig. 4. A. M. Roentgenogram taken 6 months after medial splinting showing solid union.

At the present time the method seems suitable for selected cases. Whether its field of application will broaden with more extensive use remains to be determined. The procedure offers a solution for the treatment of simple fractures of the femur that are situated just below the greater trochanter in which it is difficult to overcome and control the medial displacement of the distal fragment. Also comminuted fractures in this area, which ordinarily require long surgical procedures for fixation by plates are suited for the medullary method. Indications may be recognized in slanting and comminuted fractures of the up-

per end of the humerus that are difficult to treat. The method may be considered in treating fractures of both bones of the lower leg at the junction of the mid third which, under other forms of treatment, may require prolonged immobilization that prohibits early motion at the ankle joint, and in which non-union may occur if the fragments are not perfectly aligned.

There are several features of the method of medullary fixation that have come under discussion. The question is raised as to the danger of infection from introducing a long metallic splint into the medullary canal. German operators claim that such danger is minimized by the insertion of the splint at a distance from the site of the fracture. In the 7 cases reported herein in which the fractures were opened no infection was encountered. The routine use of penicillin of course, minimizes such danger.

The advisability of using the method in open fractures has been discussed. Some operators as Boehler (2) believe that its use is limited in these fractures. Other operators, as Ehalt, have reported excellent results in open fractures. In 1 of the cases included in this paper the fracture was an open one in which a fragment had protruded for as much as 6

Fig. 5, left. M. S. Roentgenogram showing refracture of the humerus with angulation.

Fig. 9. C. N. Roentgenogram taken 3 weeks after medullary nailing, showing callus formation.

inches outside the wound for a period of more than 6 hours before the medullary splinting. There was no unfavorable reaction following the fixation.

The necessity of the removal of the splint is another question that may be raised. Most patients prefer to have foreign material removed. When tantalum is used the removal of the splint may not be considered necessary.

Whether callus formation takes place earlier with consequent accelerating of the healing process as Kuentscher and other operators have claimed has been much debated. Boehler (2) Schneider and Swiss operators (1) have noted that the development of callus was slow and Boehler found that non-union not infrequently resulted. It would naturally be concluded that callus formation would be stimulated as the result of the complete and uninterrupted immobilization provided by this method. In 1 of the 7 cases being reported which was a fracture of both bones of the lower leg the appearance of callus in the third week after medullary fixation was particularly striking (Fig 9).

CASE REPORTS

CASE 1. M. B. a woman aged 78 years sustained a fracture of the right femur on September 4, 1945. The roentgenographic examination disclosed a fracture at the junction of the middle and upper thirds, with medial displacement of the distal fragment and about 1½ inches of overriding of the fragments (Fig 1).

On September 11, 1945 a medullary nailing was carried out according to the following technique. An incision was made beginning just above the greater trochanter and extending downward to about 2 inches below the site of the fracture. The greater trochanter and fracture cavity were exposed and the blood clots and torn tissues were removed. A drill hole was made in the greater trochanter and enlarged by introducing a curved hemostat. The medullary nail was inserted into the medulla of the proximal fragment and driven through to the fracture site. The fragments were aligned. The nail was then driven into the medulla of the distal fragment. The deep tissues were closed with chromic catgut and the skin was closed with silk. A roentgenogram was taken to check the position.

The disorientation of the patient made it necessary to place the limb on a Brann's splint and apply 5 pounds of traction. Movement of the ankle joint and toes was begun on the day following the operation. In 1 week when the patient's mental condition had improved, the splint was removed, and she

Fig. 11.

Fig. 11. A. G. Roentgenogram showing unsatisfactory treatment of the fractures by skeletal traction.

Fig. 12.

Fig. 12. A. G. Roentgenogram taken following medullary nailing.

began to exercise the hip and knee freely and with out pain.

From that time recovery was rapid. Within 3 weeks she was walking with the aid of crutches. A roentgenogram taken on November 14, 1945 shows the callus formation in 9 weeks after the medullary nailing (Fig. 2).

CASE 2. A. M. a 79 year old male fractured the right arm on March 15, 1945. The roentgenographic examination showed a comminuted fracture of the upper humerus with displacement. Several unsuccessful attempts were made to reduce the fracture by manipulation. On March 18, 1945, an open reduction with screw fixation was carried out without success (Fig. 3).

On April 5, 1945, a medullary nailing was carried out according to the following technique. An incision was made to expose the fracture cavity and the upper end of the humerus. A drill hole was made in the humeral head and enlarged by means of a curved hemostat. A medullary nail was introduced into the medulla of the proximal fragment the fragments were approximated and the nail was driven through the distal fragment. The wound was closed and the position of the fragments checked by a roentgenogram.

Within 2 weeks the patient was using the arm and had no complaint. Union took place rapidly. A roentgenogram taken on October 11, 1945, 6 months after the medullary nailing showed solid union (Fig. 4). The patient refused to consider the removal of the splint.

CASE 3. M. S. a woman aged 35 years, refractured the upper end of the humerus on December 23, 1945. She had previously fractured the humerus on August 10, 1945. The site of the fracture was in the upper end just below the tuberosity. At that time the fracture had been treated conservatively by another physician. Union was slow and a roentgenogram taken on December 20, 1945, showed a slight amount of callus with angulation of the fragments. Figure 5 shows the refracture with a 40 degree angulation that caused a noticeable protuberance on the anterior aspect of the shoulder.

On December 28, 1945, a medullary nailing was carried out according to the technique that has been described under Case 2.

Motion was started at the elbow and shoulder on the twelfth day after the operation. In less than 3 weeks the patient was using the arm. Eight weeks after the reduction, all motions were normal except abduction of the shoulder which was limited 5 degrees. The patient had returned to work. Fourteen weeks after the reduction, abduction was limited 10 degrees but this limitation was due to the protruding end of the splint hitting against the acromion. Removal of the splint was advised. A roentgenogram taken on April 2, 1946, shows the union (Fig. 6).

CASE 4. C. N. a 9 year old child, on March 2, 1946, in a coasting accident, sustained a compound fracture of the right tibia and fibula. The fracture was of the spiral type, and the proximal fragment protruded through a lacerated wound for about 6

inches (Fig 7) It was 6 hours before the fracture was operated upon

Medullary fixation was carried out as follows A thorough débridement was performed and the fractured ends were cleaned. The medullary splint was introduced into the medulla of the proximal fragment of the tibia the fragments were aligned and the splint was driven into the medullary canal of the distal fragment. The wound was closed (Fig 8) Penicillin was advised

On March 14, 1946, 2 weeks after the reduction the patient was walking with the aid of crutches. She had no pain. The temperature was normal A roentgenogram taken on March 21 1946 3 weeks after the reduction, showed callus formation (Fig 9)

CASE 5 A. G. a male aged 51 years fractured both bones of the lower leg on February 27 1946 The fractures were of the spiral type with comminution, and the distal fragment of the fibula was displaced posteriorly (Fig 10) Reduction was attempted by another physician by the use of skeletal traction with a Steinmann pin through the os calcis but the result was unsatisfactory (Fig 11)

On February 28, 1946 medullary nailing of both the tibia and fibula was done (Fig 12) The splint was introduced into the fibula from the distal end.

In addition, 1 other subtrochanteric fracture of the femur and 1 comminuted fracture of the upper end of the humerus have been treated by medullary nailing The rapidity of recovery of motion and functional capacity has paralleled that in the cases described

SUMMARY

A series of 7 fractures of the long bones which were treated by an adaptation of the Kuentscher medullary splinting method has been reported.

The method is still in its infancy, and many of its features are under discussion. Indications for its use are not yet well defined, but it would seem to offer a solution of treatment for certain selected fractures. The method has the great advantage of providing for absolute immobilization yet at the same time leaving the adjacent joints free, thereby making possible the use of the extremity at a surprisingly early date

began to exercise the hip and knee freely and with out pain.

From that time recovery was rapid. Within 3 weeks she was walking with the aid of crutches. A roentgenogram taken on November 14, 1945 shows the callus formation in 9 weeks after the fracture splinting (Fig. 3).

CASE 2. A M, a 79 year old male fractured the right arm on March 15, 1945. The roentgenographic examination showed a comminuted fracture of the upper humerus with displacement. Several unsuccessful attempts were made to reduce the fracture by manipulation. On March 18, 1945, an open reduction with screw fixation was carried out without success (Fig. 3).

On April 5, 1945, a medullary nailing was carried out according to the following technique. An incision was made to expose the fracture cavity and the upper end of the humerus. A drill hole was made in the humeral head and enlarged by means of a curved hemostat. A medullary nail was introduced into the medulla of the proximal fragment, the fragments were approximated, and the nail was driven through the distal fragment. The wound was closed, and the position of the fragments checked by a roentgenogram.

Within 2 weeks the patient was using the arm and had no complaint. Union took place rapidly. A roentgenogram taken on October 11, 1945, 6 months after the medullary nailing, showed solid union (Fig. 4). The patient refused to consider the removal of the splint.

CASE 3. M. S., a woman aged 35 years, refractured the upper end of the humerus on December 23, 1945. She had previously fractured the humerus on August 19, 1945. The site of the fracture was in the upper end just below the tuberosity. At that time the fracture had been treated conservatively by another physician. Union was slow, and a roentgenogram taken on December 20, 1945, showed a slight amount of callus with angulation of the fragments. Figure 5 shows the refracture with a 40 degree angulation that caused a noticeable protuberance on the anterior aspect of the shoulder.

On December 28, 1945, a medullary nailing was carried out according to the technique that has been described under Case 2.

Motion was started at the elbow and shoulder on the twelfth day after the operation. In less than 3 weeks the patient was using the arm. Eight weeks after the reduction, all motions were normal except abduction of the shoulder which was limited 15 degrees. The patient had returned to work. Fourteen weeks after the reduction, abduction was limited 10 degrees, but this limitation was due to the protruding end of the splint hitting against the acromion. Removal of the splint was advised. A roentgenogram taken on April 2, 1946, shows the union (Fig. 6).

CASE 4. C. N., a 9 year old child, on March 1, 1946, in a coasting accident, sustained a compound fracture of the right tibia and fibula. The fracture was of the spiral type, and the proximal fragment protruded through a lacerated wound for about 6

MACAUSLAND MEDULLARY NAILING OF FRACTURES OF LONG BONES 89

inches (Fig 7) It was 6 hours before the fracture was operated upon.

Medullary fixation was carried out as follows. A thorough débridement was performed and the fractured ends were cleaned. The medullary splint was introduced into the medulla of the proximal fragment of the tibia, the fragments were aligned and the splint was driven into the medullary canal of the distal fragment. The wound was closed (Fig 8). Penicillin was advised.

On March 14 1946, 2 weeks after the reduction the patient was walking with the aid of crutches. She had no pain. The temperature was normal. A roentgenogram taken on March 21 1946 3 weeks after the reduction, showed callus formation (Fig 9).

CASE 5. A G. a male aged 51 years fractured both bones of the lower leg on February 27 1946. The fractures were of the spiral type with comminution and the distal fragment of the fibula was displaced posteriorly (Fig 10). Reduction was attempted by another physician by the use of skeletal traction with a Steinmann pin through the os calcis, but the result was unsatisfactory (Fig 11).

On February 28, 1946 medullary nailing of both the tibia and fibula was done (Fig 12). The splint was introduced into the fibula from the distal end.

In addition, 1 other subtrochanteric fracture of the femur and 1 comminuted fracture of the upper end of the humerus have been treated by medullary nailing. The rapidity of recovery of motion and functional capacity is paralleled that in the cases described.

SUMMARY

A series of 7 fractures of the long bones which were treated by an adaptation of the Kuentscher medullary splinting method has been reported.

The method is still in its infancy and many of its features are under discussion. Indications for its use are not yet well defined, but it would seem to offer a solution of treatment for certain selected fractures. The method has the great advantage of providing for absolute immobilization yet at the same time leaving the adjacent joints free thereby making possible the use of the extremity at a surprisingly early date.

began to exercise the hip and knee freely and with out pain.

From that time recovery was rapid. Within 5 weeks she was walking with the aid of crutches. A roentgenogram taken on November 14, 1945 shows the callus formation in 9 weeks after the medullary splinting (Fig. 3).

CASE 2. A. M. a 79 year old male fractured the right arm on March 15, 1945. The roentgenographic examination showed a comminuted fracture of the upper humerus with displacement. Several unsuccessful attempts were made to reduce the fracture by manipulation. On March 18, 1945, an open reduction with screw fixation was carried out without success (Fig. 3).

On April 5, 1945 a medullary nailing was carried out according to the following technique. An incision was made to expose the fracture cavity and the upper end of the humerus. A drill hole was made in the humeral head and enlarged by means of a curved hemostat. A medullary nail was introduced into the medulla of the proximal fragment. The fragments were approximated, and the nail was driven through the distal fragment. The wound was closed and the position of the fragments checked by a roentgenogram.

Within a week the patient was using the arm and had no complaint. Union took place rapidly. A roentgenogram taken on October 11, 1945 6 months after the medullary nailing showed solid union (Fig. 4). The patient refused to consider the removal of the splint.

CASE 3. M. S. a woman aged 25 years, refractured the upper end of the humerus on December 23, 1945. She had previously fractured the humerus on August 19, 1945. The site of the fracture was in the upper end just below the tuberosity. At that time the fracture had been treated conservatively by another physician. Union was slow and a roentgenogram taken on December 30, 1945 showed a slight amount of callus with angulation of the fragments. Figure 5 shows the refracture with a 40 degree angulation that caused a noticeable protuberance on the anterior aspect of the shoulder.

On December 28, 1945 a medullary nailing was carried out according to the technique that has been described under Case 2.

Motion was started at the elbow and shoulder on the twelfth day after the operation. In less than 3 weeks the patient was using the arm. Eight weeks after the reduction, all motions were normal except abduction of the shoulder which was limited 15 degrees. The patient had returned to work. Fourteen weeks after the reduction, abduction was limited 20 degrees, but this limitation was due to the protruding end of the splint hitting against the acromion. Removal of the splint was advised. A roentgenogram taken on April 3, 1946 shows the union (Fig. 6).

CASE 4. C. N. a 9 year old child, on March 4, 1946 in a coasting accident, sustained a compound fracture of the right tibia and fibula. The fracture was of the spiral type, and the proximal fragment protruded through a lacerated wound for about 6

suprapubic approach fails because partial prostatectomy is usually done (2, 3), thus leaving a stump of prostate and urethra which may be the seat of carcinoma. Such was the case in S P (Montefiore Hospital No 34945) in whom residual neoplasm was found in the posterior urethra and in the prostatic stump after a suprapubic total cystectomy. This patient subsequently died with multiple metastases.

The perineal approach to the bladder neck and prostate, proposed by Kuester (1) and employed by others (2, 9, 12), when it is combined with a suprapubic incision permits a truly radical extirpation of the unopened bladder with the entire prostate both seminal vesicles and posterior urethra in 1 piece (Figs. 5, 6, 7, 8). The perineal incision simplifies the mobilization of the urethra, prostate and bladder neck and affords excellent dependent drainage.

The operation is done in 2 stages. Prior to each, the patient is prepared with sulfasuxidine, colonic irrigation, and cathartics. At the first stage the right ureter is implanted extraperitoneally into the sigmoid colon by the Coffey 1 or 2 technique (5, 8). At the second stage total cystectomy total prostatectomy bilateral seminal vesiculectomy and posterior urethrectomy are performed by the combined perineoabdominal method, and the left ureter is implanted into the sigmoid colon.

TECHNIQUE FOR THE COMBINED PERINEO-ABDOMINAL OPERATION

1 Perineal incision With the patient in the exaggerated lithotomy position and a Lowley prostatic tractor in the bladder, an inverted U incision is made through the perineal skin (Fig. 2). The central tendon is identified and divided. The exposed fibers of the rectourethralis are cut, separating the bulb from the rectum. The glistening fascia of Denonvilliers is brought into view, and its posterior layer incised transversely exposing the apex of the prostate and the urethra. The posterior leaf of Denonvilliers fascia is then bluntly separated from the posterior surface of the prostate seminal vesicles, and bladder as high as the finger can reach. The urethra is isolated doubly tied and divided, as far ante-

riorly as desired (Fig. 3). The ligated proximal stump of the urethra is then drawn downward exposing the anterior surface of the prostate and bladder (Fig. 4). The puboprostatic ligaments are brought into view and cut along with other adhesions.

At this stage the trigone, the vesical neck, the prostate the seminal vesicles, and the posterior urethra have been mobilized and hang attached only to the upper portion of the bladder (Fig. 1). Bleeding vessels are tied, and the perineal skin is approximated by interrupted plain catgut sutures with a soft rubber tube for drainage.

2 Suprapubic abdominal incision With the patient flat on his back in moderate Trendelenburg position a wide transverse skin incision is made about 3 centimeters above the symphysis pubis. The anterior rectus fascia and the fascia of the external oblique are cut transversely the full length of the incision. The rectus muscles are bluntly separated in the midline and retracted laterally. In some cases, part of the pubic insertion of the rectus must be severed in order to obtain adequate exposure. The dome of the bladder is then separated from the peritoneum by sharp and blunt dissection.

The peritoneum is opened sufficiently for inspection and exploration and then closed with a continuous chromic catgut suture. The anterior, posterior and lateral walls of the bladder are freed from the surrounding tissues by sharp and blunt dissection the strands containing the various vesical arteries and veins being doubly tied and cut. The region of the bladder neck and prostate already mobilized through the perineal incision, is soon reached. The bladder now lies free attached only by the vasa deferentia and the ureters. These structures are isolated, doubly tied and cut, thus allowing the unopened bladder with its attached organs to be removed from the wound.

The ligated right ureter is left in place since its proximal portion has already been implanted in the sigmoid colon at the preliminary operation. The left ureter is implanted extraperitoneally by the Coffey 1 or 2 technique. The abdominal wound is closed in layers with the long through and through rub-

TOTAL CYSTECTOMY BY THE COMBINED PERINEOABDOMINAL METHOD

SEYMOUR F WILHELM M.D., F.A.C.S New York, New York

EXPERIENCE has shown that surgical excision offers the best hope for the cure of infiltrating carcinoma of the bladder. If the neoplasm is confined to the dome or to the movable walls and is not too extensive partial resection of the bladder may suffice. On the other hand if the carcinoma involves the trigone and region of the vesical neck or if the tumors are multiple removal of the entire bladder prostate and posterior urethra is often the only effective procedure.

In 67 cases of partial bladder resection Beer and Hyman (3-7) reported an immediate operative mortality of over 25 per cent and a recurrence rate of at least 32 per cent. Eight additional patients died eventually of carcinoma. These results clearly indicate that partial resection is frequently not sufficiently radical. carcinoma cells often infiltrate in the submucous layers of the bladder far beyond the apparent limits of the growth. The occult nature of these infiltrations unfortunately deludes the surgeon into believing that an adequate resection has been done. Such was the case with L. G. (Beth Israel Hospital No. 165289) in whom a solid neoplasm was excised from the left lateral wall with a generous surrounding rim of apparently normal bladder. However biopsies from the edge of the seemingly normal bladder wall still in the body revealed carcinoma in the submucosa. This patient was reoperated upon a total cystectomy and prostatectomy were done.

Pioneers in the field of total cystectomy have reported an operative mortality of from 18 to 59 per cent (3-6-11). This alarming prospect has deterred many urologists from ever attempting the operation. However improved technique earlier operation and the use of sulfa drugs have greatly reduced the operative risk. In the series forming the basis

of this report, 15 total cystectomies were done without an operative death.

In the first 8 cases operation was done by the Beer technique (4) in which a total cystectomy and partial prostatectomy (6 men) were done extraperitoneally through a suprapubic abdominal incision with cutaneous implantation of the ureters, in 1 stage. Although the patients withstood the operative procedure rather well they subsequently all had a good deal of trouble with the care of their ureterostomy tubes leakage of urine recurrent attacks of pyelonephritis, and calculus formation. The carcinoma was well advanced in most of the patients 4 having previously undergone less radical bladder operations. Ultimately 3 patients died with metastases, the other 5 succumbing to renal infection and uremia. The outlook following total cystectomy with cutaneous ureteral implantation is certainly far from encouraging. No patient lived much over 2 years or was able to lead a comfortable normal life.

The unsatisfactory results following cutaneous ureterostomy have encouraged us, whenever possible to implant the ureters into the sigmoid colon especially since the advent of sulfasuxidine and the other sulfa drugs. Following successful ureterosigmoid implantation, our patients have lived a comfortable normal life voiding through the rectum with control.

Infiltrating carcinoma in the region of the trigone and the bladder neck not uncommonly invades the prostate and the posterior urethra. Therefore any operation intended for the cure of such a lesion must be designed to extirpate completely in one piece the unopened bladder with the entire prostate, both seminal vesicles and the posterior urethra. In the female the suprapubic abdominal approach is usually adequate for a total excision of the bladder along with a generous portio of the urethra. In the male on the other hand, the

From the Genitourinary Surgical Service, Beth Israel Hospital, New York.

both kidneys. On May 4, 1944 the patient left the hospital in good condition voiding every 2 hours through the rectum.

He re-entered the hospital on August 10, 1944 complaining of pain in the region of the pubis, groins and thighs. Seven weeks before, the suprapubic wound had spontaneously opened with persistent purulent drainage. An x-ray film of the pelvis showed no evidence of metastasis. The wound was irrigated with Dakin solution and both sulfadiazine and penicillin were administered. Following a course of x-ray therapy to the pubic area the pain abated and the purulent discharge diminished. The patient left the hospital improved on August 26, 1944.

He was again admitted to the hospital on December 10, 1944, for further revision of the suprapubic sinus and left 2 days later. He re-entered the hospital on January 15, 1945 suffering from lobar pneumonia. During this time, the wound was packed and irrigated and gradually healed except for a pinpoint sinus tract.

On June 8, 1945 there was moderate bulging of the suprapubic wound. The general condition was excellent, the patient voiding every 2 or 3 hours through the rectum, with good control.

The patient remained well and on September 15, 1945 the wound had practically healed. When last seen at the Follow up Clinic on June 6, 1946 the patient had no complaints and was in good health.

Fig. 2. Perineal skin incision with tractor in place.

CASE 11 (Beth Israel Hospital No. 168686) This 65 year old man first entered the hospital on December 8, 1944 complaining of frequent and painful urination for the past 9 months. He had noticed that his urine was cloudy and had for some time been treated with urinary antiseptics and prostatic mas-

Fig. 3. The prostate is exposed prior to the mobilization of the urethra.

SURGERY GYNECOLOGY AND OBSTETRICS

Fig. 1. Diagram showing the approximate extent of mobilization attained through the perineal incision.

ber drainage tube from the perineal wound coming out in the midline.

Five of the 6 patients operated upon by the perineoabdominal method with ureterosigmoid implantation, are living comfortably voiding through the rectum with good control. The remaining one (Case 12) suffered from an advanced carcinoma and died 5 months after operation with recurrent neoplasm filling the pelvis.

CASE REPORTS

CASE 9. (Beth Israel Hospital Nos. 160361 and 160362) This 61 year old man entered the hospital on February 3, 1944, complaining of frequent painful bloody urination for the past 3 months. About 8 months before he had undergone a 2 stage supra pubic prostatectomy.

Cystoscopic examination revealed a large tumor mass on the left lateral wall of the bladder extending anteriorly and downward to the trigone surrounding the left ureteral orifice. Biopsies disclosed carcinoma. Excretory urography on February 3 showed good excretion and no abnormality of the renal pelvis and ureters. The cystogram showed an irregular filling defect on the left side of the bladder.

On February 5, 1944, a partial resection of the bladder was done. The excised specimen included the neoplasm with a generous cuff of apparently normal bladder wall surrounding it. Since the resected segment included the left ureteral orifice and part of the trigone, the left ureter was reimplanted in the posterior wall near the dome of the bladder. At the time of operation, biopsy specimens were taken from the normal-appearing edge of the trigone which remained in situ. These revealed submucous

carcinoma and, therefore total cystectomy and prostatectomy were advised.

On April 13, 1944, the right ureter was implanted extraperitoneally into the sigmoid colon by the Coffey 1 technique. On May 5, 1944, a total cystectomy prostatectomy seminal vesiculectomy and posterior urethrectomy were done by the combined perineoabdominal method. The left ureter was implanted extraperitoneally into the sigmoid colon by the Coffey 2 technique. The patient did well after operation and left the hospital on May 31, 1944.

An excretory urogram on May 28 revealed excellent excretion of both kidneys with, however, some increase in the dilatation of both pelvis and ureters. The patient improved steadily gained weight, but voided frequently through the rectum. He complained of pain over the pubis and, on August 1, 1944, re-entered the hospital for revision of a persistent draining suprapubic sinus. Biopsy of the tract showed inflamed tissue. The wound was packed and by December 1 was entirely healed. A short course of deep x ray therapy was given to the pubic area.

Excretory urography on January 26, 1945, showed fair excretion from both kidneys with dilatation of the left ureter. Blood nonprotein nitrogen on April 17, 1945 was 46 milligrams per cent.

An excretory urogram on November 26, 1945, showed excellent excretion from both kidneys and normal outlines of both pelvis. On May 14, 1946, the general condition was excellent, the patient's only complaint being frequent rectal urination.

Excretory urography on May 28, revealed excellent excretion from both kidneys and normal outlines of both pelvis and ureters.

CASE 10. (Beth Israel Hospital No. 161390) This 56 year old man entered the hospital on March 16, 1944, complaining of frequent and intermittently bloody urination of 6 months duration. On cystoscopic examination, an infiltrating partly papillary and partly solid tumor was seen on the right lateral wall, surrounding the right ureteral orifice and extending to the trigone and bladder neck. Repeated biopsies revealed papillary and infiltrating carcinoma. Excretory urography showed normal excretion of both kidneys and normal outlines of both renal pelvis and ureters. The cystogram showed a filling defect on the right side of the bladder.

On March 25, 1944, the right ureter was implanted into the sigmoid colon extraperitoneally by the Coffey 1 technique. Fourteen days later a total cystectomy prostatectomy seminal vesiculectomy and posterior urethrectomy were done by the combined perineoabdominal method (Figs. 5, 6). The left ureter was implanted extraperitoneally into the sigmoid colon by the Coffey 2 technique.

The postoperative course was smooth except for a right epididymitis with chills. An excretory urogram on April 26, 1944, showed excellent function of both kidneys with moderate dilatation of the pelvis and ureters. Another, on February 27, 1945, showed normal pelvis and ureters and excellent function of

ctomy seminal vesiculectomy and posterior urethrectomy were done by the combined perineoabdominal method. The urethra was divided 3 centimeters distal to the apex of the prostate (Figs 7-8). The left ureter was implanted into the sigmoid colon by the Coffey technique.

The postoperative course was smooth, and an excretory urogram made on November 23, 1945, showed excellent excretion from both kidneys with only slight dilatation of the left ureter. The patient left the hospital on November 25, 1945.

On January 16, 1946, the patient felt well, had gained over 20 pounds, and was voiding through the rectum every 2 or 3 hours with good control. The perineal wound was healed, but a pinpoint sinus still remained in the midportion of the abdominal scar.

The wounds healed and the patient returned to work. On May 23, he was feeling well and voiding through the rectum every 2 hours. The blood non-protein nitrogen was 36.7 milligrams per cent, and the patient had gained over 30 pounds since operation had been performed.

CASE 14 (Beth Israel Hospital No. 179761.) This emaciated 64-year-old woman entered the hospital on January 9, 1946, complaining of hematuria of over 8 months' duration. At cystoscopy an infiltrating carcinoma was found involving almost the entire trigone and extending upward on the right lateral and posterior walls. Excretory urography showed excellent excretion from the left kidney and none from the right. The lower left ureter was moderately dilated. A left nephrostomy was done on January 11, and 24 days later the entire bladder with an attached portion of the urethra was excised through a transverse suprapubic incision. Because of the precarious condition of the patient, the left ureter was not implanted into the sigmoid colon, but was ligated *in situ* just above the bladder. The right ureter was reimplanted into the abdominal skin. On

Fig. 8. Case 4. Anterior view of excised specimen. Bladder has been opened.

February 28, the poorly functioning infected right kidney was excised.

Following these operations, the patient slowly regained her strength and left the hospital on March 24, 1946, with all the wounds healed. The nephrostomy was functioning well.

On May 22, the patient had gained 8 pounds and was strong enough to do light housework. Physical examination failed to reveal any evidence of recurrence or metastases, and the left nephrostomy was functioning well.

CASE 15 (Beth Israel Hospital No. 181470.) This 57-year-old man entered the hospital with an extensive infiltrating carcinoma involving the trigone and posterior urethra and extending upward on the posterior and lateral walls of the bladder. On March 22, 1946, Dr. William Ginsberg and I implanted the right ureter into the sigmoid colon. Convalescence was satisfactory, and on April 11, the entire bladder with an attached segment of infiltrated peritoneum, the prostate, the posterior urethra, and the seminal vesicles were excised by the perineoabdominal method. The left ureter was implanted into the sigmoid colon.

Following operation, the temperature was elevated, and on the fifth postoperative day, there was discharge of fecal material through both wounds. This gradually decreased in amount. Excretory urography on May 8, 1946, showed excellent excretion from both sides with mild dilatation of the right pelvis and ureter and normal outlines of the left pelvis and ureter. The patient left the hospital on May 2, 1946, in good physical condition, voiding through the rectum with normal control. A small fistula persisted which occasionally discharged fecal matter.

Fig. 9. Case 4. Posterior view of excised specimen consisting of the entire bladder, the prostate, the posterior urethra, and the seminal vesicles.

SURGERY GYNECOLOGY AND OBSTETRICS

Fig 5. left Case 3. Posterior view of excised specimen, consisting of the entire bladder, the prostate, the posterior urethra, and both seminal vesicles with vas deferentia.
Fig 6. Case 3. Anterior view. Bladder has been opened.

On December 7 cystoscopic examination showed a raised tumor mass about the size of a half dollar covered with slough, extending from the urethrovaginal junction upward to the left posterior wall of the bladder. The first biopsy showed only inflammatory tissue but a subsequent biopsy revealed carcinoma with severe inflammation. On excretory urography there was poor excretion from both sides but no gross abnormality of the kidney or ureter. The cystogram showed a marked irregularity of the inferior and left lateral border of the bladder.

On December 31, 1944, the right ureter was implanted into the sigmoid colon extraperitoneally by the Coffey 1 technique. The new stoma, however, failed to function and no urine was excreted by the right kidney. A fecal fistula formed which persisted until January 10, 1945. On January 11 a right nephrectomy and decapsulation were done. There was a gradual return of renal function and the tube was draining well on January 15.

A total cystectomy, seminal vesiculectomy, prostatectomy and posterior urethrectomy were done on February 3, 1945, with implantation of the left ureter into the sigmoid colon by the Coffey 2 technique. Pathological examination showed partly papillary and partly solid carcinoma. Following operation, urine drained through the rectum and through the nephrostomy tube. The patient continued gradually to improve and on March 3, 1945, a retrograde pyelogram through the right nephrostomy tube revealed that the right ureter now communicated with the bowel. The patient was discharged to the Outpatient Department on April 4, 1945, with a functioning right nephrostomy.

On April 6 the right nephrostomy tube was closed for 3 days without ill effect and on April 10, it was removed. On April 26 the wound was closed and healed. An excretory urogram, taken the following day, showed fair excretion from both sides; the pelvis and calyces partially visualized, were not dilated. There was a large amount of opaque material in the sigmoid colon.

By June 8 the patient had gained 50 pounds. He continued to improve remarkably and, when seen on November 3, 1945, had gained 33 pounds and was feeling well. Excretory urograms showed fair function of both kidneys. The patient voided through the rectum 3 times daily and once at night with good control.

When last seen on May 18, 1946, the patient's condition was excellent.

CASE 13. (Beth Israel Hospital No. 177383.) This 63 year old man was first seen on October 9, 1945, complaining of frequent bloody urination of 5 weeks duration. Urination was hesitant and sometimes painful. The stream was small. Five years ago, a papillary tumor of the bladder had been electrocoagulated and since then the patient had had no symptoms until the present illness.

Cystoscopy revealed considerable enlargement of both lateral lobes of the prostate, intraurethrally and intravesically. On the surface of the protruding left lateral lobe there was an elevated irregular red dened area which had the appearance of an infiltrating carcinoma. The neoplasm extended upward along the left lateral wall of the bladder and also anteriorly into the urethra for a short distance.

The patient entered the hospital on October 11, 1945, and on the next day biopsies were made and a transurethral prostatic resection was done, the visible portion of the neoplasm being removed entirely. The pathological report showed extensive papillary and solid carcinoma invading the left lateral prostatic lobe. Tissue removed from the right lateral lobe showed only benign hypertrophy. Excretory urography showed fair excretion from both kidneys. The right pelvis and ureter were normal, but the left revealed irregularity of the right lateral wall and inferior surface of the bladder with some trabeculation. The right ureter was implanted into the sigmoid colon extraperitoneally by the Coffey 2 technique, on October 19, 1945. Convalescence was uneventful and on November 1 a total cystectomy, prostate

ectomy seminal vesiculectomy and posterior urethrectomy were done by the combined perineoabdominal method. The urethra was divided 3 centimeters distal to the apex of the prostate (Figs 7-8). The left ureter was implanted into the sigmoid colon by the Coffey technique.

The postoperative course was smooth, and an excretory urogram made on November 23, 1945, showed excellent excretion from both kidneys with only slight dilatation of the left ureter. The patient left the hospital on November 25, 1945.

On January 16, 1946, the patient felt well, had gained over 20 pounds and was voiding through the rectum every 2 or 3 hours with good control. The perineal wound was healed but a pinpoint sinus still remained in the midportion of the abdominal scar.

The wounds healed and the patient returned to work. On May 23, he was feeling well and voiding through the rectum every 2 hours. The blood non-protein nitrogen was 36.7 milligrams per cent and the patient had gained over 30 pounds since operation had been performed.

CASE 14. (Beth Israel Hospital No. 179761) This emaciated 64-year-old woman entered the hospital on January 9, 1946, complaining of hematuria of over 8 months duration. At cystoscopy an infiltrating carcinoma was found involving almost the entire trigone and extending upward on the right lateral and posterior walls. Excretory urography showed excellent excretion from the left kidney and none from the right. The lower left ureter was moderately dilated. A left nephrostomy was done on January 11, and 24 days later the entire bladder with an attached portion of the urethra was excised through a transverse suprapubic incision. Because of the precarious condition of the patient, the left ureter was not implanted into the sigmoid colon but was ligated *in situ* just above the bladder. The right ureter was reimplanted into the abdominal skin. On

Fig. 8. Case 4. Anterior view of excised specimen. Bladder has been opened.

February 28, the poorly functioning infected right kidney was excised.

Following these operations, the patient slowly regained her strength and left the hospital on March 24, 1946, with all the wounds healed. The nephrostomy was functioning well.

On May 22, the patient had gained 8 pounds and was strong enough to do light housework. Physical examination failed to reveal any evidence of recurrence or metastases, and the left nephrostomy was functioning well.

CASE 15. (Beth Israel Hospital No. 181470) This 57-year-old man entered the hospital with an extensive infiltrating carcinoma involving the trigone and posterior urethra and extending upward on the posterior and lateral walls of the bladder. On March 22, 1946, Dr. William Ginsberg and I implanted the right ureter into the sigmoid colon. Convalescence was satisfactory and on April 11, the entire bladder with an attached segment of infiltrated peritoneum, the prostate, the posterior urethra, and the seminal vesicles were excised by the perineoabdominal method. The left ureter was implanted into the sigmoid colon.

Following operation, the temperature was elevated and on the fifth postoperative day there was discharge of fecal material through both wounds. This gradually decreased in amount. Excretory urography on May 8, 1946, showed excellent excretion from both sides with mild dilatation of the right pelvis and ureter and normal outlines of the left pelvis and ureter. The patient left the hospital on May 27, 1946, in good physical condition voiding through the rectum with normal control. A small fistula persisted which occasionally discharged fecal matter.

Fig. 7. Case 4. Posterior view of excised specimen containing the entire bladder, the prostate, the posterior urethra, and the seminal vesicles.

SURGERY GYNECOLOGY AND OBSTETRICS

SUMMARY

Fifteen consecutive total cystectomies have been reviewed. There were no operative deaths.

In the first 8 cases operation was done through a suprapubic abdominal incision with bilateral cutaneous ureterostomy in 1 stage. None of these patients lived much over 2 years nor did any lead a comfortable life after this operation. Three died with distal metastases or with residual neoplasm in the stump of the prostate and urethra. 5 succumbed to renal infection and uremia.

Six male patients were operated upon by the combined perineoabdominal method with implantation of the ureters into the sigmoid colon. Five of the 6 men operated upon by this plan are living comfortably voiding through the rectum with normal control. The 1 remaining an advanced case survived the operations but died 5 months later with a large residual carcinoma.

The operation is done in 2 stages at the first, the right ureter is implanted extraperitoneally into the sigmoid colon at the second stage the bladder seminal vesicles prostate and posterior urethra are removed in 1 piece through a combined perineoabdominal approach, and the left ureter is implanted extraperitoneally into the sigmoid colon. In males the preliminary mobilization of the urethra prostate and bladder neck

through the perineal incision simplifies greatly the subsequent suprapubic excision of the bladder.

The combined perineoabdominal method is recommended in men suffering from infiltrating carcinoma of the vesical neck and trigone because it permits a truly radical excision of the bladder together with the attached posterior urethra the entire prostate and the seminal vesicles.

THE SPLIT THICKNESS GRAFT—A USEFUL ADJUNCT IN TUBE PEDICLE PREPARATION

W B MACOMBER M D., Albany New York, and
HENRY S PATTON M D Oakland California

THE tube pedicle is subject to complications which may delay its use or destroy valuable tissue. The most common complications are infection due to excessive tension and hematoma formation. The answer to these serious problems is the use of split thickness graft in the donor site area, which relieves tension and also allows adequate tissue to be taken. There is no undermining necessary thereby preventing hematomas. The purpose of this paper is to emphasize a method that will prevent the numerous difficulties that arise from the ordinary methods of tube formation.

Possible complications from tube pedicle formation are (1) infection which may be caused by (a) separation at angles, (b) separation of donor site suture (c) wide undermining (d) hematoma formation secondary to undermining and (e) excessive use of suture material (2) lowering of patient's resistance through loss of blood shock and prolonged

surgery and greater morbidity due to enlarged operative field from undermining (3) decreased blood supply and possible necrosis of tube due to undermining near each end of tube pedicle.

The prevention of infection in the tube determines its usefulness. The healing of each angle is extremely important in the use of any tube pedicle flap. These angles are necessarily dangerous and invite infection because of increased local tension at the junction of four contiguous suture lines. Circulation at the angle is embarrassed and the necessary sutures do little to improve this diminished blood supply.

Many have advocated various means to obliterate the dangerous angles, such as staggering incisions, and flap advancement beneath the tube. These techniques ingenious as they may be, still call for undermining to close the donor site, and invite the complications listed.

The split skin graft over the donor site and beneath the pedicle prevents these difficulties and assures an intact angle. Angle separation

quate tissue can be taken and still the donor site be closed with ease. The length of time necessary to close the resultant defect from the formation of a large tube must also be considered. In the routine tube preparation, when the donor site is closed either with or without layer approximation a thin wide tender scar results.

TECHNIQUE

The common sites used in this clinic are abdominothoracic region inner aspect of thigh, neck-chest, and upper arm. The pro-

is eliminated because the graft produces countertraction at the angle and reduces tension at this danger point. This graft technique (Figs. 1, 2 and 3) eliminates wide undermining which greatly jeopardizes the blood supply at the center of the tube. It eliminates the use of much heavy suture material to overcome lateral flap tension and approximation. With the former methods, one was limited in the width of the proposed tube by the need for enough skin laterally to reclose the donor site. When using a split thickness graft in the donor site ade-

SURGERY GYNECOLOGY AND OBSTETRICS

posed flap is undermined down to deep fascia between two parallel incisions which determine its width. One side at a time is undermined so as to determine the amount needed for a soft pliable tube in which there will be no tension on closure. If patient is obese, this is especially important and the procedure is relatively more difficult from beginning to end. The flap is then tubed until closure is prevented by slight tension at each end. The hemostasis must be as perfect as possible for upon this depends the success or failure of the procedure. Several interrupted subcuticular sutures are used, approximately 1 centimeter apart, to prevent dehiscence of the tube. Following this, the skin edges are approximated with interrupted sutures. The tube donor site skin edges are attached to the deep fascia with interrupted subcuticular immobilizing sutures. The graft is taken from any desired region approximately 0.25 to 0.30 of an inch thick. The graft is sutured into position with a running locked suture the graft edge being closed in direct approximation and not overlapping the surrounding skin. At each corner direct tailoring of the graft is necessary so that there will be no overlapping or folding of the skin, thereby maintaining normal skin tension. Xeroform gauze is cut to the shape of the graft pattern and laid directly upon the graft. A wet gauze stent pattern assures adequate pressure. Xeroform gauze is then placed above the stent to protect the suture line of the tube. The dressing is held in position by strips of sterile adhesive or Scotch tape which will run beneath the tube and across the thigh to maintain the desired pressure. Two additional strips crossing beneath the tube diagonally hold pressure at each corner of the graft. Beneath these we have found it advisable to place small triangles of gauze stent so as to give additional pressure at each angle of the graft. Following this, two rolls of gauze slightly larger than the tube itself are placed parallel to it on each side, to give additional pressure to the graft and prevent any constriction across the center of the tube which might cause necrosis in this region. An overall immobilization dressing is used for final protection. A window may be made through the dressing to permit inspection of the tube as frequently as indicated to assure oneself that there is no embarrassment of the circulation at its center. The dressing is done on the sixth to the tenth day.

CONCLUSION

The technique which uses a split graft beneath the donor site is described. It has been used routinely for all tubes except those of the neck. The tubed pedicles so prepared show rapid healing and few complications.

GANGLIONEUROMA OF THE SYMPATHETIC NERVOUS SYSTEM

ARTHUR PURDY STOUT M D New York, New York

TUMORS composed of sympathetic ganglion cells and sheathed neurites with or without myelin have been well known for at least 76 years since Loretz in 1870 described one which grew in the mediastinum. During that time cases have gradually accumulated until now there are more than 250 on record. Without making an exhaustive search, the writer has been able to find available reports of 233 patients in the literature and to assemble 10 additional unpublished cases. A study of these furnishes a great deal of information yet even now it is impossible to gain an entirely comprehensive conception of this interesting tumor form because of the extreme paucity of follow up data. In all these reports I could find only 6 in which the case had been followed more than 3 years after removal of the tumor (14, 19, 25, 40, 64, this series Cases 1 and 3) and 4 more in which the tumor was known to have been in existence for more than 3 years without removal (11, 24, Glinski 115). This paucity of information regarding the curative value of operation is all the more lamentable when it is realized that attempts at removal or operative explorations have resulted in at least 21 post operative deaths, 11 intra abdominal tumors (2, 5, 10, 51, 59, 71, 83, 88, 106, 116, 117), 9 mediastinal tumors (49, 12, 20, 23, 26, 27, 30, 62, 114, Case 2) and 1 neck case (75). If at times at removal of these deep seated tumors are so hazardous, it would be extremely valuable to have accurate data about the results of removing them both when they are excised in whole or in part and when they are not treated at all. What little information exists will be considered here but it is so incomplete that it is indecisive.

The anatomical distribution of these tumors is shown in Table I. It confirms the general impression that the commonest sources

From the Surgical Pathology Laboratory of the College of Physicians and Surgeons, Columbia University and the Department of Surgery, Presbyterian Hospital, New York.

of origin are the great chains of sympathetic ganglia which extend from the base of the skull into the pelvis passing through the neck posterior mediastinum and the retroperitoneal regions including the suprarenal medulla. It also shows that on occasion the smaller sympathetic ganglia in a variety of situations can give rise to these tumors but that this is an event of extreme rarity. No doubt as time passes it will be found that they can arise in other places not mentioned here. This paper records for the first time finding them attached to the spermatic cord (Case 3) and in the tongue (Case 11). Other solitary examples in bizarre situations are reported by Bertini in the stomach, Lages Netto in the breast, Foster in the knee joint, Jorge and Latienda in the maxilla, Cramarossa, Fingerland and Siki, Meyer, Rundfleisch in the uterus, and questionable cases in the vulva by Lovelady, McDonald and Waugh, and in the kidney by Wright. Rarely they are associated with von Recklinghausen's disease (40, 66, 95, 120, 115, Case 12). There are a few examples with multiple tumors in the skin which may also be unusual varieties of von Recklinghausen's disease (58, 60, 81, 112). Ashanazy found a case with multiple peritoneal tumors. When these tumors involve the intestinal tract or appendix they may be diffuse proliferations which cause a giant overgrowth of a whole portion of it. This has been described by Jentzsch and Fatzer, Masson, Martinez Gutierrez, Pick and Bielchowsky, Poate and Inglis, Oberndorfer and Schultz. These tumors are not limited to man for Thomas has reported one in a codfish.

Table II shows that 60 per cent of these tumors are found before the age of 20 years with the greatest concentration in the first decade of life. Females predominate over males in the proportions of 3 to 2. Contrary to the impression gained by the earlier writers as expressed by Coenen there is no preponder

SURGERY GYNECOLOGY AND OBSTETRICS

blasts is potentially and sometimes actually malignant since 6 or 18.2 per cent of 33 cases metastasized. The third group with nodules of neuroblastoma distinct from the nodules of ganglioneuroma are fully malignant with metastases in 13 or 65 per cent of 20 cases. A somewhat similar division of the tumors into groups was suggested by Goodhart in 1918 and by Fischer in 1922 and by Scott *et al* in 1933 but without an exact tabulation of the degree of malignancy of the different forms.

It would seem from this study that it is probably always desirable to excise ganglioneuromas completely especially if they be long to the second and third groups. If ever the tumor belongs to the first group and it is found impossible to remove all of it because of its anatomical relationships it would seem justifiable to remove as much of the tumor as possible rather than to make no attempt to excise it. It is doubtful if this would accelerate its growth and it might prevent extension through an intervertebral foramen which is an extremely serious and often fatal complication and would obviate at least for a time the unpleasant effects of a very large retroperitoneal or mediastinal tumor. If it continued to grow *in situ* subsequent operations of partial removal might keep it in check indefinitely. If the pathologist is familiar with these types it should be easy to recognize them in a quick frozen section. But what is most urgently needed is more information as to the ultimate fate of many more treated and untreated cases so that the surgeon may be guided in his attack by knowledge rather than hypothesis.

SUMMARY

A brief study has been made of 233 previously published cases of ganglioneuroma of the sympathetic nervous system and 10 new ones. This shows that the common site of these tumors is along the route of the great chain of ganglia extending from the base of the skull into the pelvis including the supra renal medulla but with a few examples arising from ganglia in other situations. It is possible to divide the cases into three groups (1) a fully differentiated one which does not metastasize and which includes a great majority of

the tumors (2) a partly differentiated one which occasionally gives rise to metastases and (3) a third small but complex group made up both of fully differentiated ganglioneuromas and fully malignant sympatheticoblastomatous nodules, the great majority of which metastasize. The histological and biological features of these three varieties is displayed so far as the lamentable lack of follow up information permits.

CASE 1: E. R., white American girl, 2½ years of age. At 5 weeks of age a mass appeared on the right side of the neck. It gradually increased in size. Examination showed a soft mass extending from the jaw to the lower third of the neck. At operation March 6, 1917 a large mass was removed which extended from the thyroid cartilage to behind the sternomastoid where it reached the vertebrae. The internal jugular was posterior and the common carotid was external to it. Following operation the child was a Horner's syndrome which persisted several years but finally disappeared and on March 13, 1924, 7 years after operation, there was no recurrence. Gross examination showed a 7 by 4 by 3.5 centimeter nodular encapsulated mass. Microscopic examination revealed that the tumor was made up of rather large collections of cells which showed many signs of differentiation from sympatheticoblast to fully developed adult ganglion cell. The latter were in the minority. These cells were set in a matrix of delicate fibers which were acidophilic and resembled glia. It was impossible to know how many neurites were present. These collections were enclosed within a dense fibrous stroma in which there were certainly some Schwannian structures but the preparations were not good enough to say how many. No mitoses were recognized (Figs. 1 and 2). Diagnosis was diffuse, partly differentiated ganglioneuroma of the cervical sympathetic ganglion (Stout, 1924).

CASE 2: M. B. white American boy, 3½ years old. When 7 months of age he began to have abdominal pains. Four months before admission he began to develop cord pressure symptoms and finally was unable to sit up and had lost all sphincteric control. A ray examination showed a dense shadow in the upper left thorax. A needle biopsy showed a ganglioneuroma. Because of the paraplegia, the case was considered inoperable. Seven months later the child was operated upon at the Neurological Institute in an attempt to relieve the cord pressure symptoms which had become progressively worse. A very long encapsulated extradural tumor was found in the spinal canal extending from the upper dorsal into the lower cervical region and continuous with the chest mass through an intervertebral foramen. The child died shortly after the termination of the operation. At microscopic examination, sections of the needle biopsy (illustrated in the published paper) showed groups of differentiated ganglion cells which

Fig. 1. Case 2. Partly differentiated ganglioneuroma of cervical sympathetic. Topographical photomicrograph showing relative proportion of cells to stroma. X20.

varied in size from large cells with three nuclei to forms much smaller than normal. They did not have satellites and were set in a loose textured stroma with very few Schwannian structures. The tissue from the spinal canal showed small groups of similar cells scattered at wide intervals in a very thick dense fibrous stroma in which there were apparently many nonmedullated nerves. No special stains were available to confirm this. Diagnosis was fully differentiated ganglioneuroma of upper mediastinum with extension to spinal canal (114, 115).

CASE 3. T. F. white American male aged 25 years came to the hospital because he was rejected for employment on account of a left indirect inguinal hernia. At operation for cure of this July 28, 1927 a soft spongy mass was found loosely attached to the right spermatic cord just above the testis but separated from it. This was excised and the hernia repaired. Eleven years later there was no recurrence of the tumor. Gross examination showed a firm lobulated tumor measuring 4.5 by 3.5 by 2.5 centimeters encapsulated pallid and resembling fibrous tissue when sectioned. Microscopic examination showed that nonmedullated nerve fibers furnished with Schwannian and endoneurial sheaths coursed in various directions held together by loose textured connective tissue. Scattered at wide intervals were isolated fully differentiated sympathetic ganglion cells with satellites pigment and occasionally two nuclei. Diagnosis was fully differentiated ganglioneuroma of spermatic cord.

CASE 4. A. M. a Spanish girl 9 years old 2 years before admission had an attack of vomiting and fever. She was admitted to another hospital where a retroperitoneal orange-sized tumor was felt. Since then there had been no symptoms. On examination a firm not freely movable abdominal mass was felt just to the left of the vertebral column in the lumbar region. X-ray films showed no relation to kidney

Fig. 2. Case 2. Detail which shows undifferentiated sympathoblasts and partly differentiated ganglion cells. X205.

but left ureter was deviated laterally. Exploration by Dr. William G. Hecks done March 30, 1942 revealed a tumor 12 by 10 centimeters firmly attached to the posterior abdominal wall along the left lumbar vertebrae. Biopsy only was done. Twenty-five months later the mass was still palpable and had not apparently increased in size. Microscopic examination showed this tumor to be made up of widely scattered adult fully differentiated sympathetic ganglion cells with satellites, pigment and neurites set in a fibrous stroma containing vast numbers of nonmedullated neurites sheathed by

Schwannian cells and endoneurium (Fig. 3). Diagnosis was fully differentiated ganglioneuroma of the lumbar retroperitoneal region.

CASE 5. S.F. a 4 year old Cuban female had abdominal enlargement of 10 months duration. On examination a mass was felt which displaced the right kidney downward and the intestines to the left. The kidney function was not impaired. X-ray examination showed areas of calcification in the tumor. At operation May 11, 1943 a large solid tumor was found lying superior to the right kidney and pushing it caudad. It was encapsulated not adherent to kidney or iliac vessels. The mass was retroperi-

FIG. 5. Case 6. Differentiated ganglioneuroma of pelvic retroperitoneal region. Above: Topographical photomicrograph showing distribution of ganglion cells in the neurofibrillar stroma. $\times 30$. Below: Detail of ganglion cells, satellites and Schwannian sheaths. $\times 305$.

toneal and its blood supply came from the adrenal vessels. It was easily excised by Dr. George Cahill. The child made a good recovery and 33 months later showed no evidence of recurrence. Gross examination by Dr. Dorothy H. Andersen showed a centimeter mass measuring 9.5 by 8.5 by 7.1 centimeters and weighing 330 grams. It seemed to be made up of one large and several smaller flattened nodules. When cut open the knife grated against several areas of calcification. Microscopic examination revealed that this tumor was made up of numerous rather large groups of ganglion cells many of which were fully differentiated while some were only partly differentiated and occasionally sympathoblasts were present. In the surrounding stroma are many Schwannian and endoneurial structures which probably enclose neurites. The whole tumor has suffered from degeneration with patches of calcification so that accurate histological study is difficult (Fig. 4). Diagnosis was diffuse partly differentiated ganglioneuroma of right suprarenal gland.

CASE 6. J. LaP. white married American female of Slovak extraction, 18 years old was a primipara who was found to have a mass in the hollow of the sacrum indenting the rectum during routine antenatal examination. This necessitated delivery of the baby at term April 10, 1943 by cesarean section. The tumor was entirely retroperitoneal extending from the promontory of the sacrum to its fourth segment slightly to the left of the midline. It was firm rubbery and irregular in consistency. It was 8 centimeters long and varied from 3 to 5 centimeters in width. It had a very firm attachment to the sacral capsule and because of this removal was not attempted. The capsule was from 2 to 3 millimeters thick. Tumor biopsies were taken. The child was a normal baby. The patient recovered and was alive April 25.

FIG. 6. Case 7. Differentiated ganglioneuroma of suprarenal medulla showing tumor at the left and suprarenal cortex at the right. $\times 30$. Inset shows a partly degenerated ganglion cell and satellites. $\times 305$.

Fig. 7. Case 8. Differentiated ganglioneuroma of pelvic inlet. Topographical photomicrograph above $\times 20$ and detail of cells below $\times 205$.

1946 nearly 3 years later with the tumor apparently stationary. Microscopic examination revealed that the tumor was enclosed by a thick fibrous capsule with a small area of calcification. It is made up of numerous endoneurial and Schwannian sheaths without myelin which course in various directions at haphazard loosely held together by a delicate fibrous stroma. Scattered at rather infrequent intervals are groups of fully differentiated pigmented sympathetic ganglion cells attended by satellites. Some of them have two nuclei and many are without nuclei. The majority are normal in size but occasionally small forms are encountered. All appear fully differentiated. In one section some small rounded cells are collected about a capillary. These appear to be lymphocytes, monocytes, and plasma cells rather than an example of Scherer's development centers (Fig. 5). Diagnosis was fully differentiated ganglioneuroma of pelvic retroperitoneal region.

CASE 7. S1 22081; G. L. aged 71 years died with a cancer of the larynx and autopsy was performed at the Pilgrim State Hospital West Brentwood L.I. by Dr. Edward W. Gray. The right adrenal was enlarged to dimensions of 14 by 10 by 7 millimeters by the presence of an encapsulated medullary tumor 1 centimeter in diameter. Microscopic examination showed a tumor made up of countless interlaced nonmedullated nerve fibers enclosed within Schwannian sheaths. Scattered among these at intervals are fully differentiated ganglion cells in various stages of degeneration and generally enclosed by satellite cells (Fig. 6). Diagnosis was fully differentiated ganglioneuroma of suprarenal medulla.

CASE 8. Female aged 14 years began to menstruate 1 year before admission to Fordham Hospital. For an unstated period she had suffered from intermittent attacks of abdominal pain and a mass

Fig. 8. Case 9. Partly differentiated ganglioneuroma of cervical sympathetic ganglion metastatic in cervical lymph node. Detail showing undifferentiated sympathetic blasta and almost fully differentiated ganglion cells. $\times 205$.

in the left lower quadrant which had not changed in size. Examination showed an egg-sized hard smooth mass in the left lower quadrant a little below the umbilicus. Intravenous pyelogram showed that the left ureter was displaced outward by a retroperitoneal mass. At operation the mass lay between the left ureter and the left common iliac artery. It was excised without difficulty. The patient made a good recovery but was not followed after she left the hospital. The specimen was examined by Dr. Nathan Block. It was an irregularly globoid solid encapsulated mass 6 centimeters in diameter which on section showed a homogeneous moist light brown surface streaked with grayish yellow fine bands. Microscopic examination showed the tumor to be made up of groups of ganglion cells most of which

Fig. 9. Case 9. Tumor cells in lymph sinuses. $\times 205$.

SURGERY GYNECOLOGY AND OBSTETRICS

Fig. 6. Case 9. Differentiated ganglioneuroma (or hyperplastic ganglion) of the tongue. Above: A tangential section showing part of the lesion beneath the mucosa. $\times 20$. Below: Detail showing ganglion cells and nerve sheaths. $\times 205$.

were fully differentiated pigmented and often furnished with satellites. Large forms with two or even three nuclei could be found and also small cells which are otherwise fully differentiated. Some cells had vacuoles and appeared to be disintegrating. The ganglion cells were scattered throughout a stroma made up of numerous endoneurial and Schwannian sheaths in a fibrous framework varying from loose textured to dense. No myelinated nerves were recognized (Fig. 7). Diagnosis was fully differentiated ganglioneuroma of lumbosacral retroperitoneal region.

CASE 9. G. H. white male 30 months of age at 7 months of age had had a severe cold and the cervical

nodes enlarged especially on the left side. During the succeeding months there were a number of similar attacks with fever. Finally tremor of the head and neck developed with weakness and obstructive breathing. Examination showed numerous enlarged nodules on the left side of the neck. X-ray films of chest were negative. Finally a biopsy of one of the neck was done. Following this the nodules in the chest continued to increase reaching the size of two fists at 19 months after biopsy. (Information and material furnished by Dr. J. H. Ferguson, Syracuse University, N. Y.) Microscopic examination showed the sections to include portions of what appeared to be a lymph node which had been partially replaced by a tumor which tended to spread along the sympathetic plexus in various stages of differentiation. The ganglion cells but approached it occasionally when polar cells were formed. There were no satellite cells and the tumor cells were set in a matrix resembling unknown how many neurites were present. It was assumed that there were some because some of the cells had polar prolongations. No mitoses were found nor were there any rosettes or pseudorosettes (Figs. 8 and 9). Diagnosis was diffuse partly differentiated ganglioneuroma of cervical lymph node metastatic from the cervical sympathetic ganglion.

CASE 10. 24054, E. W., white married female aged 26 years for 11 months had suffered from increasingly severe pain in left side with extension down the legs on standing but relieved by lying down with legs pulled up. She had given birth to two children and had had no miscarriages. Examination revealed a fixed nodular mass in the left side 3 inches in diameter. At operation August 9, 1945 a solidly fixed tumor overlay the left common iliac vessels behind the peritoneum. It was decapsulated.

Fig. 7. Case 2. Photograph of area involved by neurofibroma. The dark pigmented areas are pigmented nodules.

Fig. 8. Case 2. Detail from a neurofibroma showing differentiated ganglion cells among the proliferated Schwannian cells.

inoperable and only a biopsy was taken. There was marked bleeding during the operation and the patient went into shock. She was given 3 plasma and 1 blood transfusion but died 9 hours after termination of the operation. It was not decided whether death was from shock or pulmonary embolism. There was no autopsy. (The clinical history was furnished by Dr. Leona Kasten and the pathological material by Dr. Alvin O. Severance of San Antonio, Texas.) Microscopic examination showed the tumor to be composed of great numbers of Schwannian and endoneurial sheaths growing in various directions embedded in dense fibroblastic tissue. Set in this at wide intervals were small groups or isolated units of adult sympathetic ganglion cells furnished with satellites. A few cells had two nuclei and many showed vacuolization and other signs of degeneration. A vast majority of the sheaths were nonmyelinated but at least two myelinated ones were recognized. Diagnosis was fully differentiated ganglioneuroma of pelvic retroperitoneal region.

CASE 11: Age and sex of patient were not stated. A swelling was noted for several months in the region of the circumvallate papillae. It was assumed that the swelling was an enlarged circumvallate papilla. A slide of the lesion was contributed by Miss Leila M. Hawkey, pathologist of the Royal Cancer Hospital (Free) of London, England. Microscopic examination revealed that the swelling had been produced by the presence in the submucosa of a mass composed of numerous small nerve bundles with both myelinated and nonmyelinated neurites, held together by a generous but loose textured fibrous stroma. Scattered at infrequent intervals there were isolated sympathetic ganglion cells with satellites and pigment. They appeared fully differentiated. The involved area extended diffusely and was not encapsulated. In places it had included ducts of the local serous and mucous glands. It had the appearance of a much enlarged normal sympathetic ganglion (Fig. 10). Diagnosis was ganglioneuroma of tongue.

CASE 12: C. F. a Puerto Rican girl, 21 months old ever since birth had had a raised pigmented hairy lesion which occupied the bridge of the nose, the right infraorbital region and lower eyelid and the right zygomatic area as far as the hair line. It was soft nodular elevated a centimeter in some places showed many pigment dots and had many fine silky hairs growing out of it. A large portion of it measuring 11 by 4 centimeters was excised by Dr. J. P. Webster January 3, 1930. Following this the tumor reappeared in the cicatrix and continued to grow. A second attempt to excise the recurrence was made July 25, 1930 but the child died during the operation (Fig. 11). Microscopic examination showed that in this highly complex tumor the skin was thickened by a growth composed of plexiform neurofibromatous nerves which as they approached the epidermis occasionally formed terminal neuromas containing adult sympathetic ganglion cells with satellites. In places the Schwannian cells had proliferated around the

nerves to form sheaths of atypical and quasi malignant aspect. Just beneath the epidermis were groups of pigmented mole cells. In places these were in direct continuity with the proliferated Schwannian cells (Fig. 12). This condition was evidently a manifestation of von Recklinghausen's disease in which the plexiform neurofibromas had formed multiple small ganglioneuromas in the skin. Diagnosis was ganglioneuromas of skin of face forming parts of the plexiform neurofibromas of von Recklinghausen's disease.

PLANTAR NEUROMAS, MORTON'S TOE

WILLIAM H. BICKEL, M.D. and MALCOLM B. DOCKERTY, M.D. Rochester, Minnesota

IN 1876 Morton described and cited examples of a peculiar and painful affection of the fourth metatarsophalangeal articulation. His observations and descriptions need little amplification except to emphasize that here is a condition in which the exact pathologic process is now known and the cure is in the hands of physicians. Morton succeeded in obtaining cures in this condition by excision of the metatarsophalangeal joint and surrounding soft tissues including the nerves distributed about the joint. Diseased tissues however were not identified by him.

There ensued a number of articles confirming Morton's observations (3, 4, 10) and making the condition a clear-cut clinical entity which has received his name. In an interesting lecture in 1887 on "Pain in the Feet" giving full credit to Morton and adding a few cases of his own, Mills expressed the belief that the trouble was limited to the branches of the external plantar nerve going to the fourth and fifth toes. He suggested that this nerve might be resected or stretched.

In 1893 Hoadley reported data on 6 cases of metatarsalgia. In one of his cases (II) in which the condition failed to respond to conservative treatment he performed operation. His findings were significant. Unfortunately for patients suffering from this condition these findings were not generally known for nearly 5 decades. In the case in question Hoadley exposed the digital branches of the lateral plantar nerve to the fourth toe and found a small neuroma. He then resected the nerve.

A prompt and perfect cure was obtained. He expressed the opinion that if operation was advisable excision of the nerve was simpler and recovery prompter than excision of the metatarsophalangeal joint as advised by Morton.

Robert Jones and Tuhby in a lengthy article in 1898 reviewed past literature and discussed

the subject thoroughly. Pathologically they observed a "well marked state of neuritis of the digital nerves" in 2 of their cases in which operation was performed. Apparently they missed the significance of Hoadley's observations although they referred to him in the bibliography. They held to the operation of resection of the metatarsophalangeal joint though they noted that the nerve could be destroyed by cautery, by injections of phenol or lastly by resection of the digital plantar nerve. They objected to the plantar approach to the nerve.

Not until 1940 was the thread of constructive surgical treatment and exact pathologic basis picked up by Betts of Australia who reported the true situation in a concise and valuable article. Unequivocally he attributed true Morton's metatarsalgia to a plantar neuroma, excision of which through a plantar incision produces a prompt cure.

In this country McElvenny separately came to the same conclusion as Betts and published his work in 1943. He expressed preference for a web splitting incision because of the early ambulation which this method affords. He observed that the tumor is rather on the lateral branch of the median plantar nerve which innervates the third and fourth digits.

The most recent confirming article is that of Baker and Kuhn who reported 14 operations with removal of plantar neuromas, cures being obtained.

We hope that this work may stimulate others to consider operative treatment in the care of intractable pain due to Morton's toe. We also should like to add a bit more on the histopathology of this condition.

CLINICAL ASPECTS

Typically the symptom complex known as Morton's toe is rather stereotyped and has been described many times. The patients have severe paroxysms of pain which usually arise beneath the heads of the third and fourth metatarsals and extend into the opposing

Read before the meeting of the Minnesota State Medical Association, St. Paul, Minnesota, May 1946.

SURGERY GYNECOLOGY AND OBSTETRICS

Fig. 1. Fusiform enlargements of fourth digital nerve typifying the average lesion found in Morton's metatarsalgia. Bilateral involvement.

sides of the third and fourth digits. Of the cases reviewed 1 patient had bilateral pain into the second and third digits and in 4 feet the pain extended into the fourth and fifth digits. The pain may extend up the posterior aspect of the leg as far as the hip. Most commonly the attacks come on while the victim is walking. However 5 patients studied described paroxysms of pain which came on while in bed, some being awakened from sound sleep as a result.

Paresthesias into the affected toes were experienced by 15 of the 18 patients studied. Cramping of the foot and toes was fairly common. Four patients stated that their trouble was much more frequent during warm weather than at other times and was relieved somewhat by cold applications. Vasomotor changes in the form of cyanosis of these toes have been noted in 1 case.

In this series there were 16 women and 2 men whose ages ranged from 25 years to 67 years. The majority of these patients tended to be somewhat overweight. Symptoms had been present from 3 months to 12 years, occurring in the right foot in 12 cases and in the left foot in 12 cases. In 5 of the cases the

symptoms were bilateral, and in 1 case 3 neuromas were removed. Symptoms were classified as atypical in 3 cases and questionable typical in 2 other cases.

Physical findings. In 16 of the 18 patients studied there was a well localized tender spot over the site of the neuroma. In contrast to reports in the literature when firm deep pressure with a rounded blunt instrument was exerted over the site of the neuroma, the affected toes were reproduced in the majority of patients. Compression of the ball of the foot and rough manipulation of the third and fourth metatarsals in some cases caused similar symptoms. Occasionally subjective numbness in the third and fourth toes was noted on light touch.

Treatment. Conservative treatment should always be given a preliminary trial. The resection of this nerve or neuroma may be stopped by shoes of sufficient length and width. External transverse bars or suitable padding within the shoe may relieve the symptoms. Persistent symptoms are best treated surgically.

In all but 1 of this series a plantar incision between the heads of the metatarsals was used. It is felt that since the nerves lie just beneath the plantar fascia and below the deep transverse metatarsal ligament, better exposure and a wider resection can be carried out through this incision. The proximal end of the nerve can be severed well back into the short muscles of the foot and future irritation of the inevitable amputation neuroma is avoided. The neuroma does not always lie distal enough to allow visualization through a dorsal or web splitting incision without severing the deep transverse metatarsal ligament. There occasionally is an anomalous nerve lying on the upper surface of this ligament, but none have been encountered in this series. Several neuromas have been removed which were proximal to the heads of the metatarsals in these cases; an approach through the web would have been difficult.

These neuromas may occur in 3 different sites along the plantar nerves. They may be distal to the bifurcation in the digital branches. They may be at the bifurcation of the nerve

Fig. 2

Fig. 3

Fig. 4

Fig. 5

Fig. 2. A normal fourth digital nerve showing wavy myelinated nerve fibrils with neurilemma nuclei (hematoxylin and eosin $\times 145$).

Fig. 3. Morton's metatarsalgia, early lesion showing swelling of the nerve trunk from neural and perineural edema. Only a few fibrils appear to be well myelinated (hematoxylin and eosin $\times 75$).

Fig. 4. Morton's metatarsalgia. The outstanding features of this neuroma are seen to be neural edema and a

marked proliferation of neurilemma nuclei. Perineural tissue shows edema and beginning fibrosis. One well formed vessel is seen (hematoxylin and eosin $\times 40$).

Fig. 5. Fourth digital neuroma showing some perineural edema with marked fibrosis and hyalinization. Islands of hyaline tissue are seen invading the nerve substance, which also shows residual proliferation of neurilemma nuclei. The lesion is a moderately late one (hematoxylin and eosin $\times 50$).

into its digital branches or the neuroma may be in the median branch of the plantar nerve before its bifurcation.

Healing of this incision has been prompt and complaints of minor tenderness in the scar were voiced by only 2 patients. The advantage of early weight bearing and ambulation when a dorsal or web splitting incision is made is important. It may be that with further use this approach will prove the better.

The operation is done with a tourniquet around the lower part of the leg, a large Penrose drain being wrapped about the leg at the

musculotendinous junction of the gastrocnemius muscle. After the neuroma is removed the incision is accurately and carefully closed with interrupted sutures of No. 0000 zytel. Weight bearing on the ball of the foot is allowed in 2 weeks.

Results. We cannot report perfect results in all 18 of the cases herein reported. We may have been somewhat overenthusiastic in our endeavors to relieve chronic distress in the feet. However in all of the cases recorded neuromas were proved histologically. In 1 case exploration was performed and the pa-

Fig 6 Fourth digital neuroma, approaching the end stage with the nerve difficult to identify in a mass of luxuriantly cellular collagenous and hyaline fibrous tissue (hematoxylin and eosin X78).

tient was relieved of distress although the sections were not conclusive of a neuroma. This patient was not included. Thirteen of the 18 patients were very pleased with the result, having complete relief of pain. Two patients had some but not complete relief. One patient was operated on whose history would make one suspect that she had painful osteoporosis of the foot secondary to a plantar neuroma. A neuroma was found and removed but at the time of writing the result is unsatisfactory.

Two patients have been operated on too recently to evaluate the result. The gratitude of patients who have benefited is ample proof of the value of this rather minor operation.

PATHOLOGIC ASPECTS

Grossly the neuromas presented either as pancake-like thickenings or as fusiform swellings of the involved nerve trunks. These thickenings tapered away proximally and distally into the adjacent and grossly normal nerve segments. The average size was small, with a length of about 15 millimeters and the diameter half that of an ordinary lead pencil (Fig. 1). The bulkier of the tumors was 2.5 centimeters in length and 1 centimeter in diameter while some of the smaller lesions brought the size of the involved nerve to a thickness only twice or three times that of the normal nerve.

All of the tumors were pearly white and all were encapsulated. The consistency was firm but in some of the early lesions the tissue appeared to be edematous. Cut sections failed to reveal any regions of cyst formation, which had been noted by McElvenny in his series. The location of these tumors has been described earlier in this paper.

Microscopically certain pathologic processes involved (1) the nerve trunks and (2) the surrounding connective tissue sheath (Figs. 1 to 6 inclusive). Early and late lesions were found in both locations. The commonest and the earliest nerve change consisted in interstitial edema, spotty in character associated with irregular demyelination and swelling of the entire nerve trunk. Accompanying a shortly following this there appeared to be a rather marked proliferation of the neurilemma nuclei giving a picture of pronounced cellularity. In some, the proliferation was central and in others predominantly peripheral, but in general the proliferation was quite diffuse. Like the edema the proliferative process was often spotty or focal in distribution. A coarctation of edema and proliferation in circumstances gave rise to the formation of tissue clefts or small cysts within the substance of the nerve. In long standing lesions moderate to severe degrees of fibrosis and even hyaline bundles were seen to affect the thickened nerve an invasion from without rather than a primary nerve change. Three of the lesions were classified as being early, 10 late, and the remainder showed changes of an intermediate grade. One could not always estimate the duration of symptoms from a microscopic examination of the neuromas.

As noted by McElvenny and by Baker and Kuhn the neuromas consisted for the most part of collagenous tissue encasing the abnormal nerve lesions described previously. Again what might be termed early and late changes were observed. In the early changes, perineural edema, usually marked in degree, was almost always associated with proliferation of connective tissue fibroblasts. The fibroblasts often produced a spidering of these generated and vacuolated with loss of nuclei

olar substance Pseudocyst formation was noted in 5 cases in which high grades of edema were present Edematous collagen seen in the early stages was replaced by the hyaline substance of long standing lesions the end result being a perineural scar which as noted previously tended to invade the substance of the encased nerve, the fibers of which often became widely separated as a result

All of the lesions appeared fairly vascular microscopically In older ones the vessels appeared thick walled and sclerotic with endarteritis and occasionally thrombosis In the early stages edema was often present in the walls of the vessels suggesting the effect of trauma rather than that of any special lesion like thromboangitis obliterans

Pathogenesis Practically all of the patients who have Morton's toe are women Almost all of them had been in the habit of wearing small high heeled shoes and had resorted to the more homely but hygienic slipper for relief of their foot trouble Two of our patients were men one wore narrow shoes because his feet were too wide The other dated his trouble to a period when he was working in a war plant and was forced by plant regulation to wear ill fitting steel capped boots These and other features point to trauma and weight bearing as the prime causes of the affliction Traumatic edema of the nerves causes swelling and demyelination which further expose the nerves to trauma and complete a vicious circle Proliferation of the nerve fibers and of the perineural fibrous tissue is but a natural consequence of this edema and local irritation Although complete scarring is the theoretical end result, enough nerve fibers escape so that in none of our cases did the pain disappear with the passage of time But why should the fourth digital nerve be selected for the development of the neuroma? Betts set about to discover the reason and developed his hypothesis on an anatomic basis His findings were confirmed by McElvenny and by Baker and Kuhn we have personally substantiated them in a number of dissections The principle is demonstrated in Figure 7

The fourth digital nerve unlike its neighbors, is of double derivation being formed through the anastomosis of branches from

Fig. 7 Diagram made from an actual dissection showing the dual derivation of the fourth digital plantar nerve to the transverse sling across the belly of the flexor brevis muscle Anchoring of the nerve resulting from this anatomic relation is supposed to lead to trauma of the nerve

both medial and lateral plantar nerves It is consequently somewhat thicker than its mates—a fact which in itself might indicate increased vulnerability to trauma But more importantly the arc described by its two constituent branches forms a transverse sling across the outer or superficial aspect of the flexor brevis digitorum muscle Whereas the other digital nerves lying as they do in deep grooves between the muscles of the foot, enjoy a certain degree of mobility in a longitudinal direction the fourth nerve is more or less anchored posteriorly Stretching of the aforementioned loop occurs during dorsiflexion of the foot and toes and in walking the degree of stretch is intensified by contraction of the enclosed flexor belly

Finally in all fairness to the opposition it must be admitted that the offending loop is sometimes absent in these cases and that

SURGERY GYNECOLOGY AND OBSTETRICS

tumors of comparable nature affect the other branches of the plantar nerves. Baker and Kuhn expressed the belief that in some of these cases nerve irritation was brought about by anomalous positions of the nerves in relation to the transverse metatarsal ligament.

SUMMARY

The affliction formerly called Morton's toe or Morton's metatarsalgia has its pathologic basis in a tumefactive perineural fibrosis of the fourth digital nerve of the foot. Degenerative as well as proliferative nerve changes along with neural and perineural edema are additionally present. The lesion may affect digital nerves other than the fourth; the predilection for which may be determined by ana-

tomies peculiarities in composition. There is considerable evidence that trauma from weight bearing in small or otherwise ill-fitting shoes is responsible for the pathogenesis of the lesion. In intractable cases the most promising treatment is resection of the affected nerve.

ANTERIOR TRANSPLANTATION OF THE POSTERIOR DELTOID FOR SHOULDER PAISY AND DISLOCATION IN POLIOMYELITIS

PAUL H. HARMON, Ph D M.D., F.A.C.S., Huntington West Virginia

TRANSPLANTATION of muscles at their superior attachment or origin for any purpose has not been widely practiced or attempted. Since the orthopedic surgeon performs muscle and tendon shifts most frequently in patients with residual paralysis from poliomyelitis it would be expected that the need for shifting the origin of muscles would be encountered for the most part in this group of patients. Ober has described three operative procedures that may be utilized to restore some of the abduction power lost at the shoulder by paralysis of the deltoid. By one method the origin of all or a portion of the pectoralis major is transferred to the spine of the scapula. In another technique the short head of the biceps and the long head of the triceps are transferred to the region of the acromion process. This author also recently described the same method employed in this case, but he did not use it for the cure of paralytic dislocation at the shoulder. Steindler's shift of the forearm flexors is well known.

Lange transplanted the origin of the vastus lateralis to the external surface of the ilium in lateral hip muscle palsy. Legg shifted the origin of the tensor fasciae femoris backward to the iliac crest to improve abduction at the hip. The results from these two latter procedures have not been spectacular possibly because of overwhelming paralysis in other hip muscles. It has been recognized though that such origin transplants contract actively after the operation. Silfverskiöld described a technique for transplanting the origins of the long head of the biceps and the semimembranosus and the semitendinosus downward into the posterior femur for flexion contracture

of the knee. Girard described an operation transplanting the origin of the hamstring muscles to the symphysis pubis to increase adduction power.

Although it is well recognized that portions of the deltoid may atrophy from the effects of poliomyelitis there is no description of the end results of cases in the literature in which the origin of the remainder of the functioning deltoid has been transplanted to improve the abduction power of the arm. In the case the outcome of which after 4 years is recorded in this report the origin of the remaining functioning posterior third of the deltoid was transferred from the scapular spine to an anterior site corresponding to the normal origin of the anterior deltoid (see Figs. 2 and 3). This transplant effected a cure of dislocation of the upper humerus which occurred habitually when the patient contracted the remaining posterior third of the deltoid in attempting abduction prior to the transplantation. The posterior third unopposed by the middle and anterior third pushed the humeral head anteriorly as it contracted along a line posterior to this structure (see Fig. 2). It was obvious that an anterior and more direct line of contraction would utilize the function of the remaining fibers more effectively and at the same time would tend to restrain the humeral head. The effectiveness of the posterior deltoid prior to transplantation in this case was further reduced by the mechanical disadvantage produced by dislocation.

REPORT OF CASE

R. M. male aged 11 years was first seen in 1940 3 years after an acute attack of anterior poliomyelitis. The acute paralysis was said to have involved the whole arm on the right side. He had received efficient and continuous after-care and had recovered a fair degree of muscle power in the right arm. His appearance at the time is shown in Figure 1a. There was extensive muscle atrophy around the right

From the Section of Orthopaedic and Traumatic Surgery, The Catholic Clinic, and The Robert Packer Hospital, Sayre, Pennsylvania.

SURGERY GYNECOLOGY AND OBSTETRICS

Fig. 1 a, left. Appearance of patient prior to operation. Note the prominence of the humeral head with the arm at rest at the side. b Maximum abduction possible before operation. The humeral head is dislocated anteriorly.

Fig. 2. The drawing illustrates the anatomic situation of the functioning posterior deltoid prior to its transplantation. Note the relation of the humeral head to the muscle.

Fig. 3. Anatomy of the transplanted deltoid remains. When the transplant contracts it retains the humeral head in the glenoid as well as exerting more direct pull in abduction in neutral and the frontal plane.

Fig 4 a, left Appearance of the patient 4 years after operation when the right arm is held at right angle abduction b Hyperabduction as carried out at the same time interval. Note hypertrophy of the deltoid transplant and the increased range of active motion

shoulder and in the arm and forearm of the same side. The humeral head could be seen and palpated with ease since the anterior and middle portions of the right deltoid were reduced to nonfunctioning fibbons. The posterior deltoid remained functional but its mass was less than that of the corresponding portion of the normal left deltoid. The right biceps brachii was functioning but its strength was inadequate. The wrist was semiflexed. The only muscle power remaining in the forearm was the atrophied weakened long flexors and extensors of the thumb and fingers. Of the group of wrist extensors and flexors only the weakened flexor carpi ulnaris remained. The grasping power of the fingers was inadequate due to inability to fix the wrist. Another major mechanical difficulty with the right upper extremity was a pathologic anterior dislocation which occurred whenever the patient attempted to abduct the left arm (see Fig 1b). Due to the combined effects of muscle weakness and mechanical disadvantage of dislocation the right upper extremity was useless. The indications were to stabilize the joint and to improve the function of the upper arm and shoulder.

On December 16, 1940 an arthrodesis of the proximal carpals to the right radial epiphysis was done and a tenodesis of the right upper humerus carried out by burying the scarified upper tendon of the long head of the biceps under osteoperiosteal flaps raised from the acromioclavicular groove. Although protected adequately after the operation the right shoulder again began to dislocate during the spring of

1941 and within a few more months it was obvious that restraint by the atrophic biceps tendon was not sufficient. The radial carpal arthrodesis improved the function of the hand to a marked degree.

On April 6, 1941 transplantation of the posterior deltoid origin was performed. An S-shaped curved incision was made extending from the middle third of the clavicle slightly downward but chiefly backward to the middle of the scapular spine. Flaps of skin and subcutaneous tissue were raised superior and inferior from the line of incision. The active posterior third of the deltoid was detached subperiosteally from its scapular origin and freed distally on a plane beneath the muscle to about half its length. This maneuver was carried out carefully to avoid injury to the branches of the axillary nerve. In this instance these branches were unusually long and allowed good mobilization of the deltoid remnant. The outer third of the clavicle was bared by periosteal dissection. The free former origin of the muscle flap was then anchored by many interrupted stitches of cotton to the outer clavicular site. The wound was closed and the arm retained in a frontal plane in 10 degree abduction by a body and arm plaster pipe.

SURGERY GYNECOLOGY AND OBSTETRICS

The upper half of the arm portion of the cast was removed after 3 weeks, the stitches removed and light massage and active motion begun. The whole cast was removed after 12 weeks and the arm supported upon an aero-plane brace. Active abduction exercises were continued. The patient could easily hold the arm against gravity for a few minutes at 6 weeks but he continued to wear the brace for protection for 4 months more. The transplanted deltoid continued to improve in function. When last seen in March, 1946 almost 4 years after the transplant the function of the right shoulder was nearly normal. Abduction could be performed smoothly against considerable added resistance and the degree of abduction could be maintained against both gravity and added resistance at any height. There were no jerky throwing motions such as were present prior to operation. Figures 4 a and b show his appearance at this time as he held the arm at two levels of abduction. By this time the transplanted posterior deltoid had hypertrophied to a muscle mass of at least three times its size prior to operation. There has been no recurrence of dislocation at the right shoulder since operation had been performed.

An additional bone grafting operation to span the distal ulna and carpus to the fifth metacarpal for preventing increasing ulnar de-

viation of the hand was done a year previous to the last observation. The graft was fixed to the ulna and fifth metacarpal with two vital lum screws at each site. This procedure achieved its purpose.

SUMMARY

A case report is presented demonstrating the result after 4 years of transplanting the origin of the functioning posterior deltoid to an anterior site in poliomyelitic paralysis of the middle and anterior portions of this muscle. Habitual dislocation of the shoulder has not recurred since the operation. The transplanted muscle has hypertrophied on use to more than three times its mass prior to operation. The function of the shoulder has been virtually normal during the last 2 years of observation.

PROBLEMS OF NURSES AND DOCTORS

THE primary purpose of this editorial is to provoke thoughtful consideration of the growing schism between the medical and nursing professions. An effort will be made to enumerate and to analyze some of the difficulties that have arisen; one approach to their solution will be suggested.

There is real dissatisfaction on the part of many doctors with the nursing profession and there is similar dissatisfaction on the part of some nurses with the doctors. This situation is unfortunate. It seems to be growing worse. In fact, one of the leading surgical associations of the country has recently appointed a fact-finding committee to enquire into the degree and character of the surgeons' complaints. In any co-operative endeavor, both partners lose when friction occurs. It is important then to separate our real problems from imaginary ones and to seek the solution of these real difficulties with determination and good will.

To begin with, it is obvious that there is not just a single point of difference between the doctors and the nurses. The relationship between these two groups varies greatly in different communities. The complaints of the surgeons in Chicago are not identical with those of their confrères in Boston, Dallas, or Hagerstown. There are, however, certain basic dissatisfactions. These are widespread and easily recognized. The first is that doctors everywhere complain about the inadequate number of nurses and about the high cost of nursing care. Furthermore, most doctors are not in sympathy with the rising educational requirements of the nursing schools. On the other hand, the leaders in nursing (the heads of schools, associations, and licensing boards) are provoked with the doctors for this lack of sympathy. Finally, many nurses, particularly the older ones, are keenly aware of a loss of *esprit de corps* in their group.

There are insufficient nurses to meet the needs of our civilian population. This is due to several factors, such as the increasing demand of the public for nurses, the requirements of the Government services, and the failure of nurses after discharge from the armed services to return to civilian work. The most important factor is the failure of the profession to attract and to hold young women. This failure is primarily an economic one. The period of preparation is out of proportion to the compensation given graduate nurses. An additional factor that applies only to nurses continuing in their field is the ever increasing boredom of their task. The doctor has three great forces to hold his interest in his work; one is the increasing responsibility of a growing practice; a second is the en-

SURGERY GYNECOLOGY AND OBSTETRICS

larging financial reward and a third is the mental stimulus of keeping up with advances in medical knowledge. The average graduate nurse has none of these stimuli to enliven her work. For her the glamor of the uniform soon fades and she does the same work for the same pay year in and year out. The leaders of the nursing world have not devised any method of making the work of the graduate nurse in a reasonably interesting or increasingly responsible

Although many people complain about the cost of nursing care the fact remains that graduate nurses are underpaid. This difficulty arises from an improper distribution of work. No method has been developed for relieving the highly trained graduate of that part of her work that can be done by less skilled workers. During the recent War the Nurses Aids showed how much can be accomplished in this direction but are these exceptional women continuing to work in our hospitals? If not what steps are being taken to replace them? Under the present allocation of work it is impossible to pay nurses adequately or to provide nursing care to patients at a reasonable cost.

Another widespread criticism of nursing schools, associations, and boards is that the effort to raise the educational requirements for pupil nurses has been pushed too fast and too far. In all fairness, however it must be said that the road travelled by the nursing profession has been a long and ever broadening one. The leaders have tried to keep nursing education abreast of the rapidly advancing front in medical knowledge. They have recognized the increasing complexities of scientific medicine and have insisted on higher and still higher qualifications for the young woman who wanted to study nursing. They have expanded and increased the number of didactic courses in the curriculum of the pupil

nurses. They have encouraged universities to foster schools of nursing. They have pressed for the goal of a college degree as a prerequisite for nurses' training. This laudable effort has much to commend it but there are at least two undesirable consequences that make it imperative for the leaders in nursing education to pause and take their bearings. These unfortunate results are first, the failure of this program to attract and to hold an adequate number of young women to meet the needs of the country and second the nurse of today is not being trained primarily to care for the patient. The situation in the field of education of nurses poses a dilemma for the leaders. Medicine is becoming increasingly complex, hence the need for more and more education, but each additional didactic course in the curriculum leaves less time for the pupil nurse to learn bedside care.

It seems clear that the kernel of this problem lies in the failure of the directors of nursing to devise ways of passing along part of the nurses' work to subordinates. In the practice of medicine this is being done constantly. A fitting illustration is the matter of transfusions. Thirty five years ago a blood transfusion was considered a surgical procedure and was performed in the operating room by a surgeon with two assistants. Then, as the indirect method was perfected transfusions were entrusted to a resident and were carried out in the patient's room. Later the interne took over and now in many hospitals the blood is matched in the blood bank and the transfusion is given by a nurse. Directors of nursing policies have been so intent on increasing the educational content of the curriculum that they have not devised ways of providing trained personnel to relieve the graduate nurse of unimportant tasks. Probably eighty per cent of the actual nursing care of the average patient can be done by high

school graduates who have had a short period of practical training. It is equally true, however, that there are seriously ill patients and also there are administrative positions that require highly intelligent, highly educated nurses.

The final complaint that was noted at the beginning of this article has to do with one of the intangibles—a loss of *esprit de corps*. This is reflected in the feeling of many nurses that they are no longer participants in a profession, but merely employees. The doctors are largely to blame for this condition. The leaders in nursing are partly to blame for they have neglected the graduates and in some institutions catered to the cadet nurses with great partiality. All of us have been too busy during the War to give much time or thought to the nurses, but the war is over now and every surgeon worthy of the name should make a real effort to win back the enthusiasm

and good will of the nurses with whom he works.

It is not the intention of this writer to make definite recommendations for the solution of the difficulties that have been considered. It would be presumptuous for any single person to do so. The correction of these problems is primarily the responsibility of the leaders in nursing. To assist these leaders is an obligation of every doctor. The schism that has developed between the nursing and medical professions is not irremediable; it can be closed. It is imperative that steps be taken to do so. In fact, the present situation offers a wonderful opportunity for intelligent leadership to perfect the integration of the two professions. Let us then critically examine the conditions in our own community and seek the solution of our mutual problems with courage, common sense, and above all in a spirit of good will.

STONEWALL ACK'NT GOT'N FORT' ED ON THE FLANK ROAD IN ANY VCN OF HIS LINE OF BATTLE.

THE SURGEON'S LIBRARY

THE BOOK SHELF

SHENANDOAH TRAGEDY

WILLARD BARTLETT A.M. M.D. D.Sc. St. Louis, Missouri

MY own compelling interest in Thomas J. Stonewall Jackson and the tragedy of 1863 was aroused by a visit to General Custis Lee, brother of the great leader at Lexington Virginia, when he was president of Washington and Lee University. A young friend and I had just graduated from college when we decided to ride our bicycles from Central Illinois to the Shenandoah Valley and explore that historic region which had been soaked with the best of Southern and Northern blood. It was just twenty nine years after the unspeakable misfortune of which I write an event which may have determined the outcome of the war one which certainly shook the military world.

The little city of Lexington seemed very lovely that summer day when General Lee, a stately gentleman just past middle life took me up to the Virginia Military Institute for one of the most stimulating experiences of my life. We stood in the class room in which Jackson had taught during the ten years which preceded the secession. I shall never forget Lee's recital of the incident of cadet impatience to be off as soon as war had been declared. The teacher is said to have cautioned them against haste then to have offered to lead them when the proper time arrived at which the fifteen year old boys screamed with merriment on hearing such war like words from their always moderate and peace loving teacher. When the proper time came he did lead them marching away bravely together the cadets to graves in the Valley the leader to that Valhalla which is the eternal home of all heroes.

Thomas J. Jackson was born in Clarksburg West Virginia (a part of Virginia itself until it seceded) on January 21 1824. He was orphaned at seven grew up on a farm was appointed to West Point at the age of eighteen though his preparatory education had been poor he never having reached a high school grade. He graduated

at West Point in 1846 took part in General Scott's campaign from Vera Cruz to Mexico City was twice brevetted for good conduct later had army duty at Fort Hamilton, New York and Fort Meade Florida. He resigned from the army in 1851 then taught philosophy and artillery tactics for ten years at Virginia Military Institute. He was an earnest member of the Presbyterian church was greatly interested in slaves and conducted a Sunday school for them.

Jackson was a tall spare man with a full beard singularly handsome but a man of few words. He was twice married first to Miss Eleanor Junkin and secondly to Miss Mary Ann Morrison.

A few days after the secession of Virginia General Jackson took over command of the troops at Harper's Ferry a few weeks later he became commander of a brigade and remained one until Bull Run where he acquired the title Stonewall. There he was made Major General. In November of 1861 he took command of the Shenandoah Valley and that portion of Virginia northwest of it his speculity being rapid movements against one enemy then another keeping them all bewildered. In December 1862 he was advanced to the rank of Lieutenant General, commanding the right wing of the Confederate Army.

The campaigns which brought him most fame seem to have been Bull Run, Richmond, Manassas, Harper's Ferry, Antietam and Chancellorsville. This brilliant tactician lived but thirty nine years as it happened because on May 1 1863 Lee ordered him to attack Hooker at Chancellorsville, causing the latter to withdraw into the wilderness to establish new lines. Next day he was early again on the march and highly successful then between eight and nine o'clock of that moonlight Saturday evening he rode forward to reconnoiter but when returning his party was mistaken for Federal troops and was fired on by the 18th North Carolina regiment of Lane's brigade the General receiving wounds that proved fatal eight days later.

Dr. Bartlett is professor emeritus of clinical surgery Washington University School of Medicine.

SURGERY GYNECOLOGY AND OBSTETRICS

THIS WAS JONATHAN JACKSON
1841-1863

One bullet entered the right hand, two the left arm, the latter cutting the brachial artery and shattering the humerus. The General's horse plunged beneath the limb of a tree which struck the rider in the face but one of his officers caught the reins and the wounded man fell into his arms. Companions took off his blood soaked garments and tried to bandage the wounds while others sought Surgeon General McGuire of the Stone wall brigade who was nearby. Jackson was bleeding, and in great pain supported by officers on

each side, while shells and bullets flying about threw men, officers and riderless horses into complete disorder. He was undismayed, however though bleeding profusely and deathly pale when he issued his last order "Pender must hold out to the last." He begged to be down so a litter was made, but when one of the bearers of it fell the General pitched to the ground incurable, a fresh serious injury to his chest.

McGuire, who had found him by moonlight coming through the trees met him with an an-

balance. The General was still bleeding profusely though he remained calm self-controlled and expressed sympathy for others. McGuire placed his finger on the left brachial artery and held it there during the ride in the ambulance during which time whiskey and morphine were administered. Two and one half hours after the wounding McGuire made an examination. Then by two o'clock Sunday morning in a hospital Jackson under blankets, again got whiskey and water. A little later chloroform was given after which a bullet was taken from his right hand which had been fractured and his left arm was amputated high entailing a simple quick bloodless circular operation. The other bullet had entered the outside of his forearm just below the elbow to come out the opposite side above the wrist. The few slight face wounds were dressed, then the General delegated authority to General Stuart after which he slept several hours.

Monday morning he was free from pain and hopeful. Some hours later he suffered right chest pain resulting according to the Surgeon General from the litter fall though no lesion was discovered and this pain was gone a few hours later. Tuesday morning he was removed in the ambulance and arrived at the Chandler House about 8:00 p.m. where he died five days later. He ate fairly well after his arrival slept the entire night and on Wednesday was thought to be improving. He felt well was cheerful, had his wounds dressed and then asked when he could return to battle. At day light Thursday however he was in great pain and McGuire found a right pleural pneumonia. *Cupping mercury antimony and opium* were employed. His wife arrived then and nursed him to the end. All wounds were dressed Friday he breathed with difficulty there also was great exhaustion. On Sunday morning May 10 1863 his wife told him that recovery was doubtful he then expressed his wish to be buried in Lexington after stating that he had hoped that some Sunday would be his last day on earth. Then his mind began to wander and he gave murmured army commands, his last words being "Let us cross over the river and rest under the shade of the trees."

The remains were taken to Richmond for a public funeral, then to Lexington for burial. In 1855 a bronze monument was erected to his memory in Richmond it having been paid for wholly by English subscribers who greatly admired this American military genius.

Eighty three years have now elapsed since Jackson's wounding. It is only natural that we surgeons of three generations should entertain a composite opinion of surgical thought as it has developed since that time and speculate on the treatment and prognosis in a like accident as of today. (None of this is to be taken as hypercritical since Hunter McGuire was a distinguished surgeon whose son Stuart I am proud to claim as a friend.)

We must consider hemorrhage early amputation anesthetic asepsis systemic antiseptics and information regarding impending death.

1 Hemorrhage left the Civil War surgeon helpless as far as replacement therapy was concerned indeed its control was limited to pressure cautery ligation or amputation.

2 Today it is considered unlikely that gangrene will follow destruction of the brachial artery particularly if a paravertebral block dilates the collaterals. Surely prolonged observation of the ischemic arm previous to amputation would be justified particularly after profuse bleeding and shock.

3 Chloroform though admittedly dangerous was of course the accepted anesthetic of the period. A form of nerve block today would take its place and at the same time centripetal shock impulses would be prevented from reaching the already damaged nerve centers.

4 The Civil War was over long before the thought or practice of antiseptics or asepsis reached America from its European birthplace. I heard my own father some twenty years later enthuse frequently over the appearance of *laudable pus* after amputations.

5 The pneumonia which was apparently the last straw today could have been easily controlled by sulfonamides. I suppose if not almost certainly by penicillin. Systemic antiseptics had not been dreamed of in 1863.

6 Today we are not given to warning the patient of impending death so one fails to see how the General's chances of recovery were enhanced by frequent depressing messages on this subject from many of the group about him.

REVIEWS OF NEW BOOKS

THE small volume *Cancer of the Scrotum in Relation to Occupation* by Henry puts on record observations of the author which may indicate that certain specific agents are, under industrial conditions, the main factors in the production of epithelioma. Cancer of the scrotum contributes more than 8 per cent of all deaths caused annually by cancer of the skin and only 0.25 per cent of all the deaths caused by cancer of all sites.

Percival Potts in 1775 quoted from Ramasimus a first reference to chimney sweepers cancer. He also stated that "cancer of the scrotum and testes is a peculiarly liable to which chimney sweepers are or carcinoma. A high incidence of cancer of the scrotum among industrial workers of certain trades as cotton mule spinners, was observed by Wilson in 1907. Carcinoma or ulceration of the skin occurring in chimney sweepers or workers handling pitch tar or tarry compounds received statutory recognition in 1907 and was added to the 3rd schedule of the Workmen's Compensation Act. Cutaneous epithelioma occurring in workers coming in contact with mineral oil paraffin or their residue was made compensable in 1914.

The Factories Act of 1930 made epitheliomatous ulceration of the skin a reportable disease. From 1920 to 1943 3,333 cases were reported of which 1,355 or 40.6 per cent were scrotal lesions. The percentages of scrotal lesions reported in the following industries were coke oven workers 47.6 per cent, coal gas workers, 31.6 per cent, tar distillery workers 19.8 per cent and pitch workers 16.4 per cent. It was further found that 1,306 or 38.8 per cent of 3,333 notifiable cutaneous cases occurred in the cotton trade (cotton mule spinners) resulting from contact with mineral and shale oil. Seven hundred and ninety three or 64.5 per cent of the scrotal lesions were reported in the cotton mule spinner workers. The mortality rate of 1,638 cases of scrotal malignancy between 1911 and 1938 was 4.5 per million population or 98 per cent. In addition it was found that cutaneous carcinoma following the commencement of occupational work occurred after 49 to 50 years. In the case of cotton mule spinners, the lag period varied from 15 to 35 years, 1 case occurred after 65 years. The average death age in 163 cases was 61.6 years. It was however impossible to make any de-

ductions of value because so many factors influence the death age. The different ages an employee would enter his occupation, the changing of occupation, the unknown carcinogenic substances in new industries make the information obtained from the death age regarding the time it takes for the carcinogenic substances to act most unreliable.

The treatment recommended for scrotal carcinoma was local excision or radiotherapy. Removal of the inguinal glands was recommended as a vast adjuvant policy because many of the palpable inguinal glands are only inflammatory. Deep therapy aimed at lessening the inflammation. Deep therapy aimed at not permitting a biopsy. In a series of 155 patients with primary scrotal malignancies, 93 of 60 per cent died of metastases within a month to 4 years with or without operation (some refused surgery).

Some suggestions were made regarding the prevention of carcinogenic substances from reaching the body of the worker. Also quarterly or biannual physical examinations would pick up scrotal cancer cases much earlier. Some workers dislike to report genital sores or lesions. Cleanliness, adequate protection, protective clothing and baths were recommended as prophylactic measures. Early treatment offers the best hope of cure.

LESTER W. RUSK

THE contributions of the frontier military surgeon William Beaumont to the physiology of digestion are a source of pride to every American surgeon. He was our first great physiologist and the first to make a contribution of enduring value. His work with Alexis St. Martin is well known and his own records of those classical experiments have been made readily available by a recent reprint. The reprint book *William Beaumont's Formative Years* contains two diaries kept by Beaumont, the one recording his medical observations and experiences, and the other excerpts from his general reading and his own philosophy. They cover the period immediately preceding his arrival at Mackinac Island and provide an interesting picture of his activities as a military surgeon during the not too glorious War of 1812. The quotations from the medical authors admired by Beaumont provide the reader with a graphic picture of the scientific fare that was available to the backwoods surgeon and scientist as a result of his own contribution shines the more brightly. Every physician who admires scholarship should read this book.

COLLECTIVE REVIEW

THE PARATHYROID ADENOMA

A Study of 322 Cases¹

EDGAR H. NORRIS M D F.A.C.S Detroit, Michigan

SURGICAL management of the parathyroid adenoma holds a place among the recent triumphs of modern surgery. Operative removal of the adenoma is the only effective treatment for this lesion and because of the striking metabolic and skeletal effects with which the neoplasm is associated, the surgical results are often dramatic.

The entire history of the parathyroids extends through a relatively brief period and is encompassed by no more than 65 years. In 1880 long after the gross anatomists had completed their charting of the organs and parts of the body the tiny parathyroid glandules were discovered by Sandstrom a Scandinavian histologist. Eleven years later in 1891 Gley was the first to demonstrate that these glandules were both anatomically and physiologically distinct from the thyroid. From the point of view of clinical medicine and surgery parathyroid history is even shorter and a considerable part of the story has been derived from experience gained in dealing with the parathyroid adenoma.

De Santi (1900) and Benjamins (1902) are often credited with having been the first to describe primary tumors of the parathyroid glands however in the light of present knowledge their descriptions are not entirely convincing. De Santi did not report on the histology in his case. And the tumor in Benjamins case was as large as a child's head! What is more despite the fact that the tumor in both cases was very large neither

author noted the association of any skeletal changes. Several other observers of about the same period (Kocher 1899 Langhans, 1907 de Quervain 1909) reported cases of cervical tumors that may have risen from the parathyroids, but, again the evidence of origin is not clear.

The more secure history of the parathyroid adenoma began about 40 years ago and during the first 3 decades of the present century scattered reports of some 30 cases appeared in which a parathyroid tumor was found at autopsy. Probably the earliest record of a case that we may today accept as one of a parathyroid adenoma was that presented by Erdheim in 1903. A year later in 1904 Askanazy was the first to associate a parathyroid tumor with skeletal lesions, and thereafter the combined incidence of an enlarged parathyroid and the lesions of osteitis fibrosa generalisata came to be recognized. However it was not until after the first surgical removal of a parathyroid adenoma by Mandl, a Viennese surgeon in 1925 that widespread practical interest in these related maladies was stimulated. Consequently the history of the clinical surgery of parathyroid disease is rather recent and has been crowded into the brief period of the last twenty years.

Since Mandl's communication of 1925 there has been a rapidly growing list of case reports and the majority have come from surgical clinics. Up to the present time more than 300 cases have been reported and the available information regarding parathyroid adenomas is considerable. However

¹See Appendix.

because no single investigator has had the opportunity to study more than a few cases, it is not surprising that our more accurate ideas have been slow in formulating and that our fundamental and practical knowledge of the parathyroid adenoma has developed gradually. In the present study we have assembled the recorded information and data and have completed a comprehensive analysis that categorically summarizes our knowledge in a manner which may guide us in securing satisfactory answers to those problems which are still unsolved.

MATERIALS AND METHODS USED IN THE PRESENT STUDY

Adenomas of the parathyroid glands have been reported since 1903. In Table I, we have brought together data from the case reports that have appeared in the literature during the 43 years from 1903 to 1945 inclusive. Table I includes the original and basic data from which the statistical analyses of this article have been derived.

Because this article is concerned with the parathyroid adenoma only and because at times in the past there has been a tendency to confuse adenomas with hyperplastic states of the glandules, we have criticized each report editorially and have admitted to the tabulation every case that in our judgment could justifiably be included. Even with this degree of critical analysis, as will be pointed out later a few cases are included among the small group of 'multiple adenomas' about which there may be some discussion. These few cases have been dealt with carefully so as not to prejudice the statistical calculations.

Although, of necessity the data have been compiled from a great many sources, and although the records on certain features are incomplete for many of the cases, we are of the opinion that the quantity of data is sufficient to justify the conclusions reached. For the quality of the records we can assume no more responsibility than to suspect their accuracy whenever exaggerated departures from evident tendencies are noted. In order critically to minimize the application of editorial judgment and to place the greater responsibility upon the original records, each problem has been approached mathematically and from several points of view with the use of illustrative tables and charts.

STATISTICAL ANALYSIS OF THE RECORDED DATA

General incidence of the adenoma. Apparently no exact figures have been published to indicate the incidence of parathyroid adenomas either in groups of individuals or in series of surgical cases.

Of the 322 cases included in Table I, 78.9 per cent of the adenomas were removed at operation and 21.1 per cent were discovered at autopsy (Table II).

Single and multiple adenomas. In the total group of 322 cases more than 1 adenoma was found in 20 instances, or in 6.2 per cent of the cases. These may be identified in Table I for a superior 1 (1) has been placed before the serial number of each case of multiple adenomas. Because this group in which more than 1 adenoma was found was small and since in most of the cases features were present that laid them open to question as true adenomas, they will be considered separately in our further statistical calculations. Before this decision was reached, however the effect of the inclusion or deletion of this small group was tested and found to be negligible. Their distribution by decades was much like that for the cases of single adenomas (1 is found in the second decade 1 in the third, 3 in the fourth, 9 in the fifth, 5 in the sixth, and 1 in the seventh). Weights are recorded in only 5 of the 20 cases. Sixteen of the cases (80.0%) of multiple adenomas were in females and 4 in males (20.0%).

In the great majority of cases the parathyroid adenoma was a single lesion that developed in, and therefore involved, only 1 of the parathyroid glandules. A single adenoma was found 502 times in the total group of 322 cases, a relative incidence of 93.8 per cent.

Location of the adenoma. The side of the neck in which the adenoma was found is recorded in 251 cases. In 132 (52.6 per cent) the adenoma occurred on the right side and in 119 (47.4 per cent) it was found on the left side of the neck. In 197 cases the location was further defined to indicate involvement of the superior or the inferior glandule (Table III). In 84 cases (42.7 per cent) the adenoma was located in the region of the right lower parathyroid in 81 cases (41.1 per cent) in the region of the left lower parathyroid in 18 cases (9.1 per cent) in the region of the right upper parathyroid and in 14 cases (7.1 per cent) it was located in the region of the left upper parathyroid.

A single adenoma in an aberrant position was found in 30 (10.7%) of 281 cases. In 19 (63.3 per cent) of these 30 cases the adenoma was located in the mediastinum in 9 (30.0 per cent) within the substance of the thyroid gland and in 1 (6.7 per cent) behind the esophagus.

Weight of the adenoma. The weight of the single adenoma is recorded in 80 of the total group of 322 cases. These 80 cases are arranged in Table IV. A study of Table IV shows that the weights of the individual tumors varied through an extreme

range. The smallest tumor weighed only 0.4 gm. while the largest attained a weight of 120 gm. The average weight was 12.47 gm and the mean weight for this series was 7.0 gm.

Size of the adenoma. The size of single adenomas is recorded with three dimensional measurements in centimeters for 143 cases. Since the majority of these tumors are roughly ellipsoidal in form, their approximate volume in cubic centimeters can be calculated by the application of the formula we used in computing the size of the parathyroids and the lateral thyroids in human embryos and fetuses

(Norris, 1937) The formula is $\frac{\pi}{6} a b c$, in which a , b and c represent the three diameters the results from the application of this formula are recorded in Table V

As may be seen in Table V the estimated volume of the individual tumors in this group of adenomas varied through an extreme range. The volume of the smallest tumor was 0.11 c.c. while that of the largest was 111.3 c.c. The average volume was 9.72 c.c. and the mean volume for this series of 143 adenomas was 3.97 c.c.

Form and other gross pathological features of the adenoma. In form adenomas of the parathyroid are not as variable as they are in size and weight. Generally they have the form of an ellipsoidal body with three unequal diameters and in this respect the adenoma resembles a normal parathyroid (Fig. 12). However in the case of the adenoma there is a tendency for the diameters to approach equality and certain of the tumors have been nearly round. Some adenomas are bilobed and others are angular bodies. Probably the average dimensions of the adenomas thus far described may be stated to be approximately 3.2 x 2.1 x 1.7 cm.

As regards their other gross features parathyroid adenomas are apparently rather similar. They are usually moderately soft, smooth of surface, and encapsulated. Through the capsule they are likely to be grayish brown in color. The cut surface tends to be moist and homogeneous in texture and yellowish or reddish brown in color. The depth of the red tone of course depends upon the vascularity of the tumor and at times hemorrhagic areas are present.

Age incidence. The age of the patient at the time the adenoma was discovered is stated in 316 of the group of 322 cases. This data is summarized in Table VI.

Parathyroid adenomas have been found in each decade from the second to the eighth inclusive no cases have been reported in children under 10 years of age or in adults over 80. Of the patients

in the second decade (the youngest age group) 5 were 14 years old 2 were 16 4 were 17 4 were 18 and 3 were 19 years old. The oldest patient was operated on at 77 years of age. The maximum incidence occurred in patients between 40 and 50 years of age and the incidence in both the fourth and the sixth decades was high and at approximately the same level. Seventy per cent of the adenomas have been found in patients between 30 and 60 years of age. Of the single adenomas the percentage incidence by decades was as follows: second decade, 6.0 per cent third 13.5 per cent fourth 18.2 per cent fifth 29.5 per cent sixth 21.6 per cent seventh 8.5 per cent and eighth decade 2.7 per cent.

Sex incidence. Sex is reported in 317 cases of the 322 in this series.

The predominance of females over males is evident in both groups as shown in Table VII it being in the ratio of approximately 3 to 1 in the group of single adenomas and 4 to 1 in the group of multiple adenomas.

Incidence of associated osteitis fibrosa generalisata and renal lithiasis and/or calcification. Observations were recorded regarding the presence or absence of associated skeletal and renal changes in each of 314 cases included in Table I. The incidence of these associated maladies is summarized in Table VIII. It is striking that only 1.5 per cent of 322 cases failed to show a degree of skeletal or renal change of clinical importance.

DISCUSSION

Incidence of the adenoma in groups and according to geography age and sex.

As to its general incidence it may be said that although the parathyroid adenoma is not a common tumor within the present medical generation the primary hyperparathyroidism with which the lesion is associated has become a well defined clinical entity. Despite this fact the malady continues to be recognized rather late in its course.

This is regrettable for as with most diseases the clinical results are better in those cases that come under early management before deformities and irreparable damage have developed. Probably the general incidence of this tumor is greater than is suspected.

As to its incidence in groups it is perhaps just as well for the present that we have no figures to indicate the incidence of parathyroid adenomas either in groups of individuals or in series of surgical cases. This is true because it has been common experience that the incidence of the lesion has risen sharply whenever the threshold of suspicion has been lowered and whenever diagnostic

¹Cases of parathyroid adenomas discovered after the statistical analyses of the 3 cases included in Table I had been concluded.

acumen has become more keen. It is probable that figures collected a decade hence may express more accurately the actual incidence of the lesion.

With regard to the incidence at autopsy and at operation it may be pointed out that during the period of about 20 years after Askanazy described the association of an enlarged parathyroid with skeletal lesions, 26 adenomas were reported as postmortem findings. Following the first surgical removal of an adenoma by Mandl in 1925 the clinical picture of primary hyperparathyroidism became better defined, interest was stimulated and, so far as the number and source of the reported cases is concerned, the statistical incidence of the tumor was altered greatly (Table II). Thus, in the period of over two decades from 1903 to 1925 96.3 per cent of the adenomas were autopsy specimens and only 3.7 per cent were removed at operation whereas in the 10 years from 1926 to 1935 more than 80 per cent of the reported cases came from surgical clinics and less than 20 per cent from the postmortem room and in the decade from 1936 to 1945 approximately 88 per cent of the reported tumors were operative specimens while only about 12 per cent were discovered at autopsy. These figures become the more significant when account is taken of the fact that during the latter period (1936 to 1945) on the average, 50 per cent more cases were operated on each year

than came to surgery during each year of the earlier period. Although the number of cases of parathyroid adenoma reported in the literature probably represents but a fraction of the true incidence, such records as we have suggest that in the future still more cases will be recognized and that a greater number will be given the benefit of earlier surgery.

As to the geographic incidence it may be stated that considerable numbers of cases have been reported from particular clinics, but this must not be taken as evidence to support the contention that the incidence of parathyroid adenomas is influenced by geography (Wildner and Howell 1936 Cope 1944). What is true however is the indisputable fact that this tumor has been recognized more commonly in those places where men are diagnostically alert to the problems presented by this cryptic malady.

Our information regarding the age incidence of parathyroid adenomas is based upon data that record the age of the patient at the time the tumor was discovered at operation or at autopsy. The scattergram and frequency curves shown in figure 1 emphasize two points. Taking into consideration the entire group of 295 cases, the maximum incidence occurred in patients 45 years of age with a large accumulation on either side of this age for 70 per cent of the adenomas were found

INTERNATIONAL ABSTRACTS OF SURGERY

Fig. 1. The frequency curve proper to the scattergram has been grouped and plotted as the upper one drawing the middle line. Note that this curve has a peak at 45 years. The other two curves, in broken lines, have been taken from Figures 2 and 3 and have been drawn into Figure 1 for easier comparison (Total of 295 adenomas.)

TABLE II—ADENOMAS FOUND AT AUTOPSY AND AT OPERATION

Period of age	No. of cases	Total no.	Autopsy	Operation
0-10	1	1	1	0
10-20	1	1	1	0
20-30	1	1	1	0
30-40	1	1	1	0
40-50	1	1	1	0
50-60	1	1	1	0
60-70	1	1	1	0
70-80	1	1	1	0
80-90	1	1	1	0
90-100	1	1	1	0
Total	10	10	10	0

in patients between 30 and 60 years of age. Figure 1 also indicates that nearly twice as many cases were discovered in the years of late childhood and early adult life as were observed within the seventh and eighth decades.

We were interested to learn whether the better understanding of hyperparathyroidism that has been attained during the last decade would reflect itself in an alteration of the age incidence curve.

In this end the 162 cases reported from 1936 to 1945 were studied separately and were plotted in the scattergram marked Figure 2 and a frequency curve was drawn in. Comparison of this curve with the one shown for the entire group in Figure 1 shows that the high peak of middle life has been replaced by a broader curve. Continuing this comparison another difference is apparent although in the smaller group more cases continue to appear in the early years of life than in the declining decades; there is no longer evidence of an exaggerated concentration of cases in the third decade.

To analyze further the occurrence of this disease in relation to age the 22 cases discovered at autopsy and reported between 1916 and 1945 were deleted. The 140 remaining cases were plotted in Figure 3. The curve drawn in Figure 3 has a peak at 45 years. It is characterized by a limb that ascends rather steeply during the early adult years to reach a broad plateau that extends through the middle decades and by a limb of gradual descent after the fiftieth year. The curve of Figure 3 indicates a much more even distribution of the cases through-

TABLE III—LOCATION OF THE ADENOMA

Location	Number of cases	Percentage
Right Lower	81	4.7
Left Lower	8	4
Right Upper	4	9.1
Left Upper	4	7.1
Total	97	100.0
Right	5	5.6
Left	9	47.4
In aberrant positions	30	0.7
In mediastinum	9	63.3
In the thyroid	9	100.0
Retroesophageal	4	6.7
Location not stated	20	3.7
More than one adenoma	6	6

Fig. 2. In this scattergram the number of adenomas found at each year of life have been grouped and plotted as a dot. The frequency curve of this figure also appears as the middle curve in Figure 1 (162 cases reported 1936-1945)

the life span than appeared in Figures 1 and 2. It seems likely that the curve in Figure 3 based as it is upon corrected data expresses more accurately the age distribution of parathyroid adenomas than do the curves shown in Figures 1 and 2. For reader comparison the curves from Figures 2 and 3 have been drawn in broken lines in the scattergram marked figure 1.

From the standpoint of the improving standards of clinical medicine the findings just related are most complimentary. This statistical analysis appears to demonstrate the operation of two most desirable tendencies: (1) that the duration of cases of primary hyperparathyroidism has been reduced and (2) that during recent years there has been an earlier recognition of cases both of

Fig. 3. In this scattergram the number of adenomas found at each year of life have been grouped and plotted as a dot. The frequency curve of this figure also appears as the lowest curve in Figure 1 (140 cases reported 1936-1945 as adenomas discovered at autopsy have been deleted.)

Fig. 4. The curve drawn in a solid line indicates the distribution of adenomas in the group of 317 females; note the presence of two phases in the ascending limb and the location of the peak at 45 years. The curve drawn in a broken line indicates the distribution of adenomas in the group of 80 males; note the relative simplicity of this curve and that its peak is located at about 35 years.

these tendencies appear to be direct results of a better and a more widespread understanding of the disease and its diagnostic criteria.

The sex incidence as may be seen in Table VII is such that adenomas of the parathyroid have been found 3 times as frequently in females as in males. For this significant sex difference no satisfactory explanation is found in the literature. In Figure 4 we have approached the problem by the construction of curves showing the percentage distribution in decades of 397 cases according to sex.

In both sexes adenomas begin to be recognized at about the age of puberty. Among males these tumors have been found with constantly increasing frequency through the third decade and this maximum incidence is attained in the fourth decade. Among males, adenomas have been found with constantly diminishing frequency from the fifth decade throughout the remainder of life (Figure 4).

As may be seen in Figure 4 the distribution of the cases among females is somewhat different from that among the males, starting at puberty the curve rises less abruptly for some 20 years and then ascends steeply to a maximum in the fifth decade. Throughout the later decades the incidence in females decreases constantly and precipitously.

From this analysis 4 conclusions seem justified. On the basis of sex there is a difference in the age distribution of parathyroid adenomas. The maximum incidence occurs a decade earlier in males than in females. The maximum incidence among females is greater than that among males. The ascending limb of the curve for females shows two phases since these two phases extend through and correspond to the childbearing period, it is possible that they may have been influenced or perhaps determined by pregnancy or by lactation.

Single and multiple adenomas. In the answer to the query whether true adenomas of the parathyroid are ever multiple, will be found much of fundamental and practical importance. Only 30 cases have been reported as examples of the parathyroid adenoma in which a tumor was found in more than one glandule. These cases are too few to have great statistical significance as a group. However since their distribution according to age and according to sex is much the same as obtains for the group of single adenomas, the fact that we have chosen to omit them from combined consideration with the much larger group of single tumors has not appreciably altered the conclusions reached. Indeed, if any observation argues strongly that the group of multiple tumors are true adenomas, it certainly is the fact that age and sex distribution of the two groups is so similar.

It is well known that certain conditions such as severe chronic renal insufficiency, are often associated with hypertrophy of all of the parathyroids. In such instances the parathyroid tumefaction is due to a parenchymal hyperplasia that is secondary to the underlying disease. This is therefore a secondary hyperplasia of the glandules and a condition that must be carefully distinguished from the primary hyperplasia (neoplasia) of the true adenoma. This thesis was established largely by the excellent studies of Albright and his coworkers and their published work did not appear until 1938. It so happens that of the 20 cases of multiple adenomas, only 2 have been reported since 1938!

If we study the basic data recorded for these 20 cases more carefully several points become evident. One case (Table I Serial No 75) had 4 enlarged glands, 2 that were very large and 2 that were said to be enlarged but the size was not given. In another case (Table I, Serial No 225) 3 enlarged glands were reported 1 which was definitely enlarged, was removed at operation and the 2 other enlarged glands, the measurements of which were not given, were found at autopsy. Three large glands were also found in the case recorded in Table I as Serial No 315 these were later interpreted as representing 'primary hyperplasia of the wasserhelle' cells. In 3 of the remaining 17 cases (Table I, Serial Nos. 69 102 210) no absolute measurements of the glands are recorded, and in another 3 (Table I Serial Nos. 165 166 243) the size of the second gland was such that it could fall within normal limits. In 2 cases (Table I Serial Nos 59 162) the tumors may have been more or less separate parts of one mass. There remain 9 cases (Table I, Serial Nos. 47 56 74, 77 85 122 183 195 213) for each of which the data recorded are too incomplete to permit utilization of the cases as a group for deciding an issue such as that involved in the present problem.

Finally it needs to be pointed out that among this entire group of 20 cases there were 12 in which advanced renal disease was recognized. Since secondary hyperplasia of the parathyroids is not infrequently associated with high degrees of chronic renal insufficiency the burden of proof must rest with each investigator to demonstrate the absence of renal or other previous disease in all of those cases of multiple enlargements of the parathyroid glands that are thought to be adenomas.

Only one conclusion seems justifiable although it is possible that more than 1 adenoma may develop in 2 or more glands in the same case at the same time, up to the present time the literature

has contained few convincing reports of multiple adenomas of the parathyroids that may be accepted without question.

Location of the adenoma In 1937 we published the results of an investigation of the topographic anatomy of the parathyroid glands in 93 human embryos and fetuses. The range of variability in the position of the glandules was established, and the reasons for the topographic variations were elucidated (Norris 1937). For the surgeon an exact knowledge of the embryogenesis of these glandules is important in order that he may understand the locations in which tumors of the parathyroids are to be sought. Because of their significance in this connection certain of the illustrations from our earlier study (Norris, 1937) have

Fig. 5. Left, A schematic interpretation of the morphogenesis of the third branchial pouch and its derivatives. For detailed description of units see text of article by Norris, 1937 a and b, preprimordial stage c, early primordial stage d, early branchial complex stage e, late branchial complex stage f, late branchial complex stage, (definitive form stage not included) b.c.III, third branchial cleft (ectoderm) c.a., cervical sinus (ectoderm) e.th., entodermal thymus, p.III, third entodermal branchial pouch p.III parathyroid III p.d. pharyngobranchial duct ph., pharynx r.p.d., remnant of pharyngobranchial duct th. thymus.

Fig. 6. Right, A schematic interpretation of the morphogenesis of the fourth branchial pouch and its derivatives. The median thyroid has also been included. For detailed description of units see text of article by Norris, 1937 a, Preprimordial stage b and c, early primordial stage d, branchial complex stage e, fusion stage f, isolation stage (definitive form stage not included) In the diagram the stages represented are named by a combination of the terms applied in the study of the lateral thyroid and parathyroid IV b.c., fourth branchial cleft (ectoderm) e.p.IV, fourth entodermal branchial pouch Lt., lateral thyroid m.t., median thyroid p.IV parathyroid IV p.d., pharyngobranchial duct, ph., pharynx r.p.d., remnant of pharyngobranchial duct.

Fig. 7 An arrangement of drawings based upon selected graphic reconstructions to show the usual changing relations of the derivatives of the third and fourth branchial pouches during the branchial complex stage. All of the drawings represent anterior views. The central structure in outline represents the esophagus; the U-shaped figure in outline, the median thyroid; the elongated barlike bodies in outline, the thymus. Parathyroid III is shown in solid black (diagonals where it lies behind the thyroid); parathyroid IV in simple outline; lateral thyroid, in coarse stipple (finer stipple when it lies behind or within the median thyroid lobe). (a) Graphic reconstruction of pharyngeal region of 5.0 mm. embryo. (30.) (b) Graphic reconstruction of pharyngeal region of 16.0 mm. embryo. (30.) (c) Graphic reconstruction of pharyngeal region of 7.0 mm. embryo. (30.) Note that parathyroid III has descended so that it lies in approximately the same plane; parathyroid IV (30.) (d) Graphic reconstruction of pharyngeal region of 6.0 mm. embryo. Parathyroid III has descended to the level of its usual definitive position. (33.) (e) Graphic reconstruction of pharyngeal region of 30.0 mm. embryo. This figure represents the end of the branchial complex stage and shows the parathyroids nearly isolated and in their usual definitive positions. (30.) (f) Graphic reconstruction of pharyngeal region of 24.0 mm. embryo. This figure shows the very striking growth that has taken place in the lateral thyroids and the resultant altered form of the lateral lobes of the thyroid gland. Compare the outline form of the median thyroid in this figure with the outline form of the same body in a, b, c, d, e. (X30.)

been reproduced in this article (Figures 5, 6, 7, 8, 9, 10, 11). These figures are described and explained in the individual legends. A surgeon should not consider himself competent to operate for a parathyroid adenoma unless he has a thorough knowledge of the embryology of the human pharynx and its derivatives. To determine the site of the tumor is the first problem of the surgeon as he enters the neck to treat hyperparathyroidism and, almost entirely, the various possible sites in which the tumor may be situated are determined by the mechanics of genetics in the cervical region of the individual.

Adenomas of the parathyroid glands are about equally frequent on the right and on the left side of the neck (Table III). In the series of 151 cases, 51.6 per cent (132) of the adenomas were found on the right side, and 47.4 per cent (119) were dis-

covered on the left side of the neck. However when the frequency of adenomatous involvement of the superior and inferior glandules is considered, a remarkable difference becomes apparent (Table III).

In the group of 197 cases, 83.8 per cent (165) of the adenomas were found in the region of the inferior glandule, while only 16.2 per cent (32) were located in the region of the superior glandule. Here again the distribution of the cases in which the adenoma was found in the inferior and superior positions is about equal when they are divided into right and left groups. Thus 43.7 per cent (84) of the adenomas were located in the right inferior position and 41.1 per cent (81) were found in the left lower position, 9.1 per cent (18) were located in the right superior position, and 7.1 per cent (14) were found in the left superior position.

Fig. 8. An arrangement of drawings based upon selected graphic reconstructions to show variations in the more usual definitive relations of the parathyroids and certain anomalies. All drawings represent anterior views. The central structure in outline represents the esophagus; the bilobed body in outline, the definitive thyroid; the barlike bodies in outline, the thymus. Parathyroid III is shown in solid black (diagonals where it lies behind the thyroid); parathyroid IV in simple outline (broken line where it lies behind the thyroid); lateral thyroid, in coarse stipple (finer stipple when it lies behind the median thyroid lobe). (a) Graphic reconstruction from cervical region of 60.0 mm. fetus. ($\times 10$) (b) Graphic reconstruction from cervical region of 66.0 mm. fetus. ($\times 10$) (c) Graphic reconstruction from cervical region of 83.0 mm. fetus. ($\times 10$) (d) Graphic reconstruction from cervical region of 83.0 mm. fetus. ($\times 10$) (e) Graphic reconstruction from cervical region of 65.0 mm. fetus. Note presence and location of accessory parathyroid III. ($\times 10$) (f) Graphic reconstruction from pharyngeal region of 22.0 mm. embryo. Note presence and location of accessory parathyroid III. In this figure the lateral thyroid has fused with, but has not been incorporated by the median thyroid. ($\times 30$)

In view of the extent of the migration of the anterior parathyroid that goes on normally during embryogenesis, it is not surprising that adenomas are found in aberrant positions (Figs. 5, 6, 7, 8, 9). In the series of 281 cases the tumor was found in an abnormal situation in 30 cases (10.7 per cent). In this group of 30 cases the tumor was found in the mediastinum in 63.3 per cent, imbedded in the thyroid in 30.0 per cent, and behind the esophagus in 6.7 per cent of the instances. The adenomas discovered in the mediastinum are there because the glandule from which the tumor was drawn down into the thorax by the ascending thymus.

The tumors which were imbedded in the normal thyroid grew in parathyroids that had been surrounded by the expanding thyroid during fetal life (Figs. 10 and 11).

These observations have practical value for the operating surgeon. Since the average size of a parathyroid adenoma is small, and since the extensive dissection in search of the tumor demands the utmost care, a scientific plan should guide the cervical exploration. On the basis of the frequency with which adenomas have been found in certain locations a formula to guide the surgeon's approach may be suggested. First the region of the right lower thyroid pole should be explored, then that of the left lower thyroid pole, then the region of the right superior glandule and, finally the usual location of the left superior parathyroid should be exposed. In seeking an adenoma in the region of the superior glandule it must be remembered that superior in this instance does not necessarily correspond to the upper pole of the thyroid gland, but more nearly to the midlevel of

Fig 9. Drawing of a graphic reconstruction from the pharyngeal region of 24 mm embryo. A tensor view of the anomalous undescended third branchial complex on the left side which contrasts strikingly with the normal condition on the right side. Note especially the median thyroid lobes at places where lateral thyroid bodies have been incorporated. The central structure in outline represents the esophagus the U shaped body in outline the median thyroid the barlike and ovoidal bodies in outline, the right and left thymus, respectively. Parathyroid III is shown in solid black (diagonal where it lies behind the thyroid) parathyroid IV in simple outline (broken line where it lies behind the thyroid) lateral thyroid in fine stipple for it has been incorporated within the median thyroid. (X20.)

the lateral thyroid lobe. As the dissection progresses in each of these fields the contours of the thyroid had best be carefully scrutinized in order that a tumor imbedded in the substance of the thyroid may not be overlooked. Finally in the cervical exploration the tracheoesophageal angle the retroesophageal space, and the carotid sheath on each side remain for inspection. Ultimately when the cervical exploration has been fruitless, the surgeon must open the mediastinum. Excellent descriptions of the technique of parathyroid surgery are found in articles by Churchill and Cope (1934 and 1936) and by Cope (1941).

Weight size form and other gross pathological features of the adenoma. The site of the tumor is the first problem, and the size of the adenoma be-

comes the second problem of the operating surgeon. Most adenomas of the parathyroid are relatively small soft, encapsulated tumors, they are too small, in the majority of cases, to produce local symptoms that the patient will recognize, or signs that the physician may discern in his physical examination of the neck. However it may be well to call attention to the fact that in a few cases the patient may complain of a swelling in the neck, dysphagia or the like.

Previously we have pointed out the wide variability in the size of these lesions. The smallest adenomas have been very tiny bodies while the largest have attained truly exceptional proportions. Indeed, as may be seen in Tables IV and V the 10 largest tumors in our series were of sufficient size to account for a wide disparity between the average and the mean values of weight and volume. Of course, the larger tumor will cause the surgeon no difficulty in his exploration. Therefore, from the practical point of view and in dealing with the majority of cases, it will be best for the surgeon to have in mind the mean values. For the most part he will be searching for a tumor whose weight will approach 7.0 gm. whose volume will approximate 4 or 5 cc, and whose diameters may be expected to vary from a mean of about 3.2 by 2.1 by 1.7 cm.

Pains were taken to estimate the volume of the 143 adenomas for each of which 3 diametric measurements were given. This was done because suitable data for this calculation were available for nearly twice as many tumors as were included in the group that had been weighed. Forty-four tumors had been both weighed and measured and it was interesting to note the close degree of correspondence between the weight and the estimated volume in the majority of these cases (Table V). In only 6 cases (13.6 per cent) was the discrepancy between the recorded weight and the estimated volume too great to be readily accounted for.

In our series the smallest adenoma weighed 0.4 gm. while the largest weighed 120.0 gm., and the mean weight was 7.0 gm. The biological and clinical significance of these figures may be seen in Table IV.

If a normal parathyroid gland weighs approximately 0.035 gm. then under normal conditions

TABLE VI.—DISTRIBUTION OF ADENOMAS BY DECADE

Age in Years	0-9	10-19	20-29	30-39	40-49	50-59	60-69	70-79	80-89	Total
Number of Single Adenomas		28	40	12	85	65	1	8		235
Number of Multiple Adenomas				1	9	8				18

Fig. 10 Group of diagrams representing cross sections through thyroid region to indicate variations in position of parathyroid III. These four diagrams correspond to the four position groups described in the article by Norris, 1937. Parathyroid III is shown in solid black, definitive thyroid in coarse stipple, esophagus trachea (or larynx) in fine stipple.

Fig. 11 Group of diagrams representing cross sections through thyroid region to indicate variations in position of parathyroid IV. These four diagrams correspond to the four position groups described in the article by Norris, 1937. Parathyroid IV is shown in solid black, definitive thyroid, in coarse stipple, esophagus and larynx, in fine stipple.

the combined weight of all the parathyroid tissue would be about 0.14 gm. Thus, the smallest adenoma of 0.4 gm. was more than 10 times as large as a normal glandule and approximately 3 times the mass represented by the total parathyroid tissue of the body. This small tumor was associated with a striking clinical picture in which both skeletal and renal changes were prominent.

The largest tumor with its weight of 120.0 gm. was nearly 3,500 times as large as a normal glandule and approximately 850 times greater than the mass of all the parathyroid tissue of the body. Adenomas of 7.0 gm. representing the mean weight of the tumors in our series, show an hypertrophy of nearly 200 times and 50 times, respectively the size of a normal glandule and the total parathyroid tissue of the body.

As Castleman and Mallory (1935) pointed out, if this new formed glandular tissue functioned in proportion to its size, some individuals would die of parathyroid poisoning like that so easily produced in animals with parathormone unless some compensating mechanism were brought into play. Using the blood calcium levels these same authors thought they could demonstrate a roughly quantitative relation between the size of tumor and degree of hyperfunction. However they stated that as the size of the tumor in-

creases the proportional effect of unit weight on the blood calcium becomes rapidly less and less.

In Figure 12 the characteristic form of an adenoma is shown in comparison to the size and form of a normal parathyroid glandule. Although the adenoma shown in this illustration may be considered typical, not a few adenomas have been much more irregular in form. Some have been irregularly bilobed or nearly separated into two distinct masses; it is certain of such cases that may have been misinterpreted as examples of multiple adenomas. From the practical point of view, however, the knowledge that lobulated tumors exist should cause the surgeon to search carefully in the vicinity from which an adenoma has been removed, if a partially detached lobule or a portion of such a tumor is not removed, the clinical result would be spoiled or possibly a second operation would be necessary.

Through the capsule the tumor has a grayish brown color. On the cut surface tones of yellowish brown are mixed with shades of red that depend upon the richness of the vascularity. Most adenomas are soft and have a texture similar to that of the normal spleen. However in some the presence of sufficient stromal tissue in the form of septal bands may considerably increase the consistency. Deposits of calcium in the capsule or in

Fig. 12. Photograph of the parathyroid adenoma removed from a patient suffering from generalized osteitis fibrosa. The adenoma weighed 3.9 gm. Note the bilobed form of the adenoma. The small object to the left is a normal parathyroid removed from the same patient.

the connective tissue septa have been observed. Hemorrhage from the thin walled vessels is certainly the most frequent complicating feature. It is probable that the cystlike spaces so commonly described are posthemorrhagic phenomena. Areas of necrosis are not commonly reported in adenomas of the parathyroid.

Fig. 13. Photomicrograph of an area from the adenoma shown in Figure 12. Note the monotonous character of the histological picture. From field to field the structure was practically the same. All of the cells are dense cells, only an occasional primordial or small vesicular cell is seen. (X400).

We have reported 1 case in which there was infarction of an adenoma, associated with the signs and symptoms of tetany (Norris, 1946). The cause of this vascular accident was not determined.

Histology and cytology of the adenoma. The structural makeup of a parathyroid adenoma is subject to variability within rather wide limits. Most characteristically the parenchyma of the tumor is arranged in irregular blocks or masses of epithelial cells. These blocks or masses are closely related and are separated from each other by an extremely delicate connective tissue stroma through which a rich network of capillaries and sinusoids runs (Figs. 13 and 14). However not a few adenomas exhibit a mixed and much more complex architecture. In some adenomas follicular structures of varying size are conspicuous (Figs. 16, 17 and 18) and in others irregular cystlike spaces are seen. Indeed in certain adenomas follicular and cystic structures may predominate, with solid portions (Figs. 13 and 14) making up a relatively minor part of the tumor.

Probably the microscopic identification of a parathyroid adenoma depends more upon the recognition of cells characteristic of the parathyroid than it does upon a characteristically typical structural pattern. In the adenomas the same cellular types are to be found as are represented in the parenchyma of normal parathyroids (Norris, 1947) and the cells tend to be polyhedral bodies outlined by very distinct cell walls (Figs. 13, 14, 15 and 16).

In 1898 Welch, after examining the parathyroid glands from 40 human cadavers at autopsy published a description of the histology of the

Fig. 14. Photomicrograph of an area typical of the greater part of a parathyroid adenoma. Note the delicate vascular stroma that separates the epithelial masses. Nearly all of the cells are vesicular cells; only an occasional primordial or dense cell is seen. (X400).

normal gland and he recognized certain distinctly different types of cells. Subsequent authors, in writing their studies have introduced other terms as suited their convenience until now the terminology applicable to the cells of the parathyroid has become regrettably confused. This confusion is particularly unfortunate from the standpoint of our present interest because there is probably no better material for the study and delineation of the functions of the cellular elements of the parathyroid than that provided by a group of functionally active adenomas. However little progress along this line can be made until a uniform and thoroughly understood terminology has been adopted. In a recent article based upon the study of 1665 human parathyroids, we have recommended a terminology for the parenchymal cytological elements of these glandules and it is hoped that the use of it may lead to an understanding of the functional attributes of the different cells (Norris 1947). When we have more information on this subject it is likely that we will be able to recognize a more constant relationship between the cytological picture of an adenoma and the associated clinical and laboratory findings. May we venture to suggest that when such a relationship can be demonstrated it probably will be much more direct constant and significant than is the relationship between the size of the adenoma and the associated clinical state? We are wont to answer this rhetorical query in the affirmative because all of the cytological types I have described (primordial cells, vesicular cells, clear cells, dense cells, dark cells, and oxyphil cells) have been found in adenomas and in many tumors particular cells have predominated almost

to the exclusion of others while in other tumors the cells have been mixed in varying proportions and include all manner of transitional forms. We are in need of more cases of primary hyperparathyroidism for which the greatest detail in the clinical history and findings have been recorded before the adenoma is removed, if a closer relationship between the cytology and functional state is to be established.

On the basis of cellular constitution the oxyphil adenoma (a tumor consisting entirely of oxyphil cells) is probably the rarest form of parathyroid adenoma (Fig. 16). Very few such tumors have been described (Hunter and Turnbull, 1931; McQuillan 1938; Cope 1944; Norris 1946). In fact, oxyphil adenomas are so unusual that some authors have contended against their existence. Care must always be exercised of course not to mistake for adenomas, those large islands of oxyphil cells that are commonly found in the normal glands of adults (Chown 1937).

The cells of certain adenomas manifest a considerable degree of pleomorphism and in some the presence of mitoses is a conspicuous finding. Indeed some adenomas show pictures that simulate invasion of their capsules by the parenchymal elements such a picture has been interpreted by us and by others as signifying only the encroachment of peripheral cords between overlying layers of the capsule. On the other hand, such observations (cellular pleomorphism, mitoses and capsular invasion?) have led certain authors to designate particular tumors as grade 1 carcinomas (Snell 1936; Alexander *et al.* 1944). From the knowledge we now possess of the parathyroid adenoma I can see small advantage in so doing indeed the recog-

Single Adenomas	80	17	7	73
Multiple Adenomas		80	16	80

nition of grade 1 carcinoma seems rather disadvantageous and confusing since these tumors do not invade extensively or metastasize nor do they behave as malignant tumors in their other characteristics. It seems preferable to regard the parathyroid adenoma as a benign tumor by definition to give up any desire to recognize a grade 1 degree of malignancy for this lesion and to reserve

TABLE VIII.—INCIDENCE OF OSTEITIS FIBROSA GENERALISATA AND RENAL LITHIASIS AND/OR CALCIFICATION IN ASSOCIATION WITH A PARATHYROID ADENOMA

Associated skeletal and/or renal disease	Number of Cases	Per cent of Total (see Table VII)

the term carcinoma for those much rarer neoplasms of the parathyroid that exhibit indubitable evidence of their malignant nature.

Histological evidence supports the concept that the parathyroid adenoma develops as a result of

Figs. 7 and 8. Photomicrographs of two areas from the same parathyroid adenoma to show varieties of histological architecture. Left, illustrates the follicular structure and the arrangement of parenchymal cords in loose lace-like pattern. Note the clearly faintly stained col-

loid in the follicles and between the cords. (X 100.) Right, illustrates a pattern made up of irregular cystic follicular structures.

In the lower right hand corner an area of more nearly solid structure is seen. (X 100.)

localized proliferative process within one glandule. Especially in the smaller adenomas a rim of normal parathyroid tissue has been seen persisting over one surface of the tumor (Castleman and Mallory 1935). In sections from larger tumors such remnants of normal parenchyma are less easily found because of the very size of the growth and in the larger tumors the normal glandular tissue may have been caused to atrophy by the growth of the adenoma.

Clinical duration and growth of the adenoma. From the foregoing pages one may surmise that exact knowledge regarding the growth of this tumor and its clinical duration would be scant. This is indeed the case. However the literature contains many observations that throw light upon the problem what is more much may now be deduced from the combined use of the data and findings we have just reviewed. For evident reasons it is important that we have precise information concerning the general biologic aspects of this neoplasm without such information there is little hope for further improvement in the clinical management of the numerous conditions of which the adenoma is provocative.

In 1934 Albright, Aub and Bauer reported a case in which there was reason to believe from the symptoms that the adenoma had existed for 30 years. At the other extreme a few cases are recorded in which there were no symptoms at all the tumor having been discovered accidentally as the result of suspicion aroused by altered blood findings in the course of an examination for other purposes. Apparently very few patients in whom an adenoma has been identified have presented themselves with symptoms extending through a period so brief as 1 year. Some patients have recognized symptoms for less than 2 years but by far the majority have histories with symptoms ascribable to the adenoma that have extended through many years prior to the diagnostic recognition of the responsible lesion. Very many patients have described symptoms that extended through a decade or even 15 or more years. There is the case of the famous Captain Martell, this man was known to have had hyperparathyroidism for 13 years and he underwent 7 operations before the adenoma was found in the anterior mediastinum. Probably it may be concluded from the reported cases that the average duration of symptoms has been from 5 to 7 years.

All of this convinces us of two things. In the first place the disease state with which a parathyroid adenoma is associated is cryptic at its onset and insidious in its progression. Secondly it must again be emphasized that reports in the

literature record the date at which the adenoma was finally discovered—a date in the majority of instances that is years after the time at which the tumor originated and began to produce its effects. With this latter conclusion in mind it will be well for us to reconsider our figures on the age incidence of the adenoma. If this is done while we at the same time have in mind the data on the weight, the size and the histology of adenomas we may extend our knowledge regarding the growth tendencies of this neoplasm.

As is shown in Table VI and in Figure 1 the age of the youngest patients at the time the adenoma was discovered was 14 years. Since it is likely that on the average these adenomas had been present for some years we may believe that they had their origin during the first decade or even during the period of early childhood. Similar reasoning applied in an effort to establish the age at the time

of onset will displace the entire incidence curve (Figure 1) to the left; the age of onset for the maximum number of cases would then be nearer 10, 15 or 20 years than at 45 years as shown in Figure 1. Further support for this conclusion comes from a review of Figure 2; it will be seen that the incidence has been modified through inclusion of only the more recently reported cases—cases that in all probability were identified nearer the time of onset than the cases discovered during earlier periods. Likewise emphatic support is given by the curve shown in Figure 3—a curve that has been altered by omitting the terminal cases in which the tumor was found at autopsy. This approach toward correction of data on the age incidence of the adenoma. In an effort to determine the time of onset has further significance if we wish to relate the onset of parathyroid ade-

Fig. 19. Photomicrograph of a typical area in an oxyphil adenoma. Note the mitotic figure. (X350)

Fig 21. In this scattergram 80 adenomas have been assembled into groups that differed by 5 gm. in weight, and distributed on the chart according to this weight grouping and according to the number of adenomas in each group.

tionship of cell types to function and more concerning the endocrine relation of the tumor to the general physiology of the body.

In summary of this analysis several conclusions seem warranted. The cryptic nature of primary hyperparathyroidism makes it impossible to determine the exact time of onset, however such knowledge as we have of the incidence and growth tendencies of this tumor seems to indicate that it may originate in a particular individual at any time from childhood to old age. Furthermore the insidiousness with which the malady progresses imposes difficulties in judging of the duration of the disease prior to recognition of the adenoma, although subject to acute clinical crises the disease is essentially chronic and slowly progressive. As the result of a wider dissemination of more accurate knowledge of the disease and its diagnostic problems, more cases of hyperparathyroidism have been recognized during the last decade than in the years that preceded. However when the cases reported between 1936 and 1945 were segregated, the weights and volumes produced scattergrams quite similar to those shown in Figures 20 and 22. Indeed as may be seen in Figure 22 the largest adenoma thus far reported occurred in an individual 25 years of age. It therefore appears that certain adenomas grow more rapidly than others (perhaps periodically) and that their size is not wholly dependent upon duration. Certainly the reports in the literature substantiate the conclusion that as the tumor increases in size its clinical effects are proportionately less.

Pathological physiology of the adenoma In the last few years considerable progress has been made in the understanding of both the normal and the pathological physiology of the parathyroid glands. A recent article by Pope and Aub (1944) presents a comprehensive review of this progress.

As we have learned the parathyroid adenoma is a benign neoplasm which in practically all, if not in all, instances affects the body's economy through the excess of parathyroid hormone generated in the tumor. The parathyroid adenoma is therefore an endocrinologically active tumor and the diseased state produced by the presence of the adenoma is the direct result of an oversupply of the hormone. So far as we know the secretion generated by the adenoma is the same as that elaborated by normal parathyroids, consequently the effects produced in the body result from the continued activity of an abnormally large amount of the secretion. In this connection it should be pointed out that there is need for more reports on the bioassay of adenomas (Moolten, Clarke and Haywood, 1937; Rutishauser 1941). Assays of more adenomas would seem to offer the best objective approach to the problem. However a note of caution may be sounded in the first place there are possible sources of error and, secondly, the findings from assays are not necessarily indicative of the behavior or of the fate of the hormone in the body.

In studying the altered physiology produced by the adenoma we become interested in the subject of mineral metabolism and its control by the endocrine glands. The recent literature contains a

Fig. In this scattergram the individual estimated volume in cubic centimeters of 140 adenomas is plotted as dot. Nearly twice as many cases were available for the construction of this chart as appear in Figure 30. Note that the adenoma having the greatest volume occurred in an individual 25 years of age. In general, this scattergram confirms the evidence recorded in Figure 30.

number of excellent reviews in this field. Since the comprehensive review of calcium and phosphorus metabolism by Schmidt and Greenberg in 1935 other studies have appeared concerned with the same topic and with the chemistry of calcification and the physiology of bone, by Greenberg (1939) Cohn, Cohn, and Aub (1942) Logan (1940) MacLean (1943) Guest and Rapoport (1941) and by MacLean (1941). In 1941 Campbell and Turner reviewed the literature on the relation of the endocrine glands to calcium metabolism, and studies on special aspects of this problem have appeared by Albright (1941) Anderson (1939) Bodansky and Duff (1939) MacLean (1941) and by Silberberg and Silberberg (1943).

Such information as we have indicates that the parathyroids can function in the absence of the anterior lobe of the pituitary gland. If there is an endocrine relationship between these two organs it is not so direct or so close as is the case with certain other ductless glands and the pituitary (Campbell and Turner 1941).

The terminal results from the action of the parathyroid hormone are well known; however the exact manner in which the hormone affects these results remains a matter of conjecture. There are two theories regarding the action of the parathyroid hormone and for each there is considerable support in the nature of experimental evidence. The theory of Collip (1932) holds that the chief action of the parathyroid hormone is directly on the solution of calcium salts from bone. On the other hand the theory of Albright (1941) postu-

lates the chief action of the parathyroid hormone to be that of promoting the renal excretion of phosphate.

The hormone acts to increase the excretion of calcium if insufficient calcium is being absorbed from the intestine. Decalcification of the bones will result. Perhaps those clinical cases that show no skeletal decalcification may find their explanation in the protection that comes from a diet rich in calcium. Why certain patients manifest a form of generalized osteoporosis and why others develop the bizarre picture of osteitis fibrosa cystica is not understood; possibly the latter condition develops in those patients in whom the loss of calcium is very rapid.

The increased output of calcium by the kidney results in supersaturation of the urine with this element. The calcium precipitates out as a phosphate salt (alkaline urine) or as calcium oxalate (acid urine) and calculi may be formed anywhere in the urinary tract. If the precipitation occurs in the lumens of the renal tubules, casts of calcium phosphate are formed. Not infrequently calcium is deposited in the renal parenchyma, which produces calcification of the kidney and a gradual impairment of renal function. Since it appears that on the whole, those cases of hyperparathyroidism that develop renal complications are milder than those with extensive osseous involvement, and since calcification of the kidney may develop early in the mild, renal calcification may progress to lethal proportions before the underlying condition is

recognized. Cope (1944) has very clearly described the ensuing picture.

The development of renal impairment alters the characteristics of the disordered metabolism. With progressive renal calcification or nephritis from ascending sepsis the kidney fails to excrete the excess calcium with which it is burdened by the overactive parathyroid glands. The excess, however, is excreted by the large bowel and the calcium level of the blood remains as before. If renal impairment continues there may be less calcium than normal in the urine.

With impairment the kidney also fails to excrete phosphate, chloride, and nonprotein nitrogen. The levels of these three substances rise in the blood. The phosphate may rise from its abnormal, low level to normal or even above. When it is above normal it may tend to depress the elevated calcium. When retention of these substances occurs the urine has a fixed low specific gravity usually without albumin. The kidney function, as judged by the phenolsulfonphthalein excretion may be but little depressed. And it is in this manner that a fatal degree of renal insufficiency may become associated with an otherwise relatively mild case of hyperparathyroidism (Mayer 1941).

Clinical complications of the adenoma. We have seen how the disease condition provoked by a parathyroid adenoma is an entity known as primary hyperparathyroidism, the result of the continued presence of an excess of the parathyroid hormone. As this state endures through months and even years of time certain complicating changes develop in the body in varying frequency and in varying degrees of intensity. The chief complications involve the elements of the skeletal system and the upper urinary tract. Indeed changes are so common in these anatomic systems that by many they have come to be thought of as the disease condition itself. In our series of 322 cases, only 1.5 per cent of the adenomas failed to produce any clinically recognizable skeletal and/or renal changes (Table VIII).

The figures in Table VIII indicate that the skeletal and renal changes may occur in particular patients either alone or together. In the present series of cases clinically recognizable changes in the bones were found in 90 per cent while the urinary tract showed involvement in only 36 per cent of the cases. The effects of the hyperparathyroidism were confined to the osseous parts alone in 60 per cent of the cases, to the urinary tract alone in only about 5 per cent and in particular patients there were changes in both the skeletal and renal tissues in a little over 30 per

cent of the cases. In addition to these common complications a few authors have described the occurrence of metastatic calcification in soft tissues other than those of the kidney.

Cope (1944) believes that complications affecting the urinary tract are more common in hyperparathyroidism than are those affecting the skeleton. He also states that renal complications are more likely to be associated with milder states of hyperparathyroidism and that the bony changes tend to be more prominent in the severer forms of the disease. Albright, Baird, Cope and Bloomberg (1934) assume that the degree of the bone changes is related to the duration of the disease rather than to its severity.

The renal complications are the direct result of the high concentration of calcium in the urine. Calcium may be precipitated out from the urine in any part of the urinary tract from the renal tubules to the bladder with the formation of casts or stones. Not infrequently the precipitation of calcium occurs in the parenchyma of the kidney itself. No matter where it occurs the precipitation leads to greater or lesser degrees of disturbance of renal function; many patients have been operated upon for calculi before the underlying condition was recognized.

The osseous changes are due to the removal of abnormal amounts of calcium from the bones. At times this results in the picture of a diffuse osteoporosis and in other cases the bizarre picture of osteitis fibrosa cystica is produced. The bones become softened and fragile so that deformities and pathological fractures occur. These pathological changes (Figs. 23 and 24) have been experimentally reproduced in animals (Yaffe 1933).

It is of interest to know that, according to Denninger (1931) osteitis fibrosa generalisata existed in America in prehistoric times. Lesions interpreted to be those of this condition were found in the skeleton of a primitive American Indian that was discovered in Northern Illinois.

Clinical features associated with the adenoma. *Primary hyperparathyroidism.* The clinical state associated with the adenoma is known as primary hyperparathyroidism. It is called primary because the adenoma is thought of as an autonomous neoplasm and the term 'primary' further distinguishes the effects produced by this tumor from other conditions in which enlargement and overactivity of the parathyroids result as secondary effects due to certain preexisting diseases (chronic renal insufficiency, rickets, etc.). By definition therefore, primary hyperparathyroidism is the clinical condition associated with and provoked by the presence of a parathyroid adenoma.

in which the signs and symptoms are engendered by the excess of parathyroid hormone secreted by this tumor

Primary hyperparathyroidism may be discovered at any period of life from midchildhood to old age. The youngest patient from whom an adenoma has been removed was less than 14 years old at the time of her operation and symptoms had been present since the age of 9 (Anspach and Clifton, 1939). The oldest patient was 77 years of age at the time of her operation (Gamberini, 1935). The maximum incidence is between 30 and 60 years.

Primary hyperparathyroidism is 3 times more frequent in females than in males.

The average duration of the symptoms prior to the discovery of the adenoma has ranged from 5 to 7 years, and the persistence of symptoms through such a long period attests the cryptic nature of the malady. The literature records 1 case in which there is reason to believe that the symptoms had existed for 39 years (Albright, Aub and Bauer, 1934).

Because, on the average, a parathyroid adenoma remains small it relatively rarely produces mechanical symptoms. Occasionally it may cause dysphagia or a feeling of fullness in the neck. Probably in no more than 10 per cent of the cases has the adenoma been palpable, or has it displaced the thyroid so that distortion of the cervical contours was noticeable. A few adenomas, in aberrant positions, have been visualized in roentgenograms of the chest.

Lassitude, asthenia, and fatigue are usually complained of and result from the muscular hypotonia that is caused by the associated hypercalcemia. Occasionally the increased excretion of calcium may produce polyuria and polydipsia. Loss of weight, and at times vaguely connected gastrointestinal symptoms, such as impaired appetite, constipation, indigestion, nausea, and vomiting may be mentioned. Among their chief symptoms some patients list pain in the extremities or pain over other skeletal parts, and a few have noted loss of height and the development of kyphosis.

This recitation serves to emphasize the fact that primary hyperparathyroidism has no specific symptoms. Indeed, the very lack of specific symptoms has made the malady clinically unrecognized except in rare instances, until its complications have become evident. The differential diagnosis in the incipient period will always be difficult and the early recognition of cases will depend almost wholly upon the enthusiasm and vigilance of the physician.

Hypercalcemia and hypophosphatemia are the two most prominent laboratory findings. Generally the blood serum calcium value will be between 11 and 16 mgm. per cent and the phosphorus value between 2 and 4 mgm. per cent, as the concentration of calcium increases in the serum, the phosphorus level is depressed. Hypercalciuria is commonly demonstrable. Studies of the serum phosphatase have not yielded such constant or dependable results, although in many cases the concentration has been elevated. Consequently any patient with indefinite complaints, with hypercalciuria, and with blood which contains an excess of calcium and a diminished amount of phosphorus should be re-examined and his condition investigated until hyperparathyroidism has been excluded.

The clinical course of primary hyperparathyroidism is characterized by its insidious onset and by its cryptic, chronic progression. The course is likely to be interrupted by such seemingly unrelated incidents as renal colics, the passage of renal calculi, spontaneous fracture of the bones, the development of postural deformities, or the appearance of tumorlike swellings on the skeletal parts. All of the latter when recognized for their true nature are the more dramatic indications of complications that develop in cases of primary hyperparathyroidism.

At times the course may be interrupted by crises during which the patient suffers from acute poisoning by the parathyroid hormone. Crises of this type are sometimes referred to as acute hyperparathyroidism. Exemplary cases have been described by Dawson and Struthers (1923), Hanes (1930), Oliver (1930), Smith and Cooke (1930), and by Alexander *et al.* (1944). In such attacks the patient exhibits restlessness, tachycardia, and prostration and may succumb. Rogers (1946) described a case in which uncontrollable vomiting preceded death. On the whole patients with primary hyperparathyroidism remain ambulatory, are disturbed by a variety of indefinite, non-specific symptoms, and progress slowly through periods of disability due to exaggerated distress from complications, to a state of chronic invalidism. This tragic course can be interrupted only by the diagnostic recognition of the condition and by the removal of the adenoma.

So prominent are the complications of primary hyperparathyroidism that they have often been regarded as the disease itself and many times therapy has been directed toward them without recognition of the underlying responsible lesion. The most conspicuous complications involve the skeleton and the kidney.

Figs. 23 and 24. Two photomicrographs from biopsies taken from the humeri of 2 patients, each suffering from the effects of a parathyroid adenoma. These figures illustrate the skeletal lesion known as osteitis fibrosa generalisata. The replacement of the marrow spaces by fibrous tissue is

well shown. In the lower part of Figure 23 numerous giant cells are scattered through the fibrous tissue. In the upper part of Figure 23 a tiny cyst is present. Near the center of Figure 24 a large cyst is seen and just above and to the right a considerable accumulation of pigment. (X 50.)

We have already seen how 90 per cent of the reported cases have shown clinically recognizable involvement of the osseous tissues. The skeletal lesion in primary hyperparathyroidism is called osteitis fibrosa generalisata a disease that manifests itself in two forms. The more common form is described by the term osteitis fibrosa cystica, because of the cystlike areas of rarefaction that appear in the bones. Very many of the bones may be affected, or the lesions may be sparsely and irregularly scattered through the skeleton. The less common form shows a diffuse decalcification of the skeletal parts and is spoken of as the diffuse osteoporotic form; the bones become flexible and rubbery in advanced stages of this condition. Although these two forms of osteitis fibrosa generalisata are recognizable, it is quite common to find evidence of each form in the same case.

Despite the fact that in our series of cases only 36 per cent showed involvement of the urinary tract Cope (1944) states that the commonest complication of hyperparathyroidism is precipitation of calcium in the urinary tract. Doubtless this apparent discrepancy is due to several facts: first, many of the cases reported in the literature developed through long periods of time; second, a better knowledge concerning the association of renal lesions has come in recent years; and finally, probably greater attention has been paid to the renal function in hyperparathyroidism at the Massachusetts General Hospital than in many other places.

The urinary system is affected in four ways in hyperparathyroidism: the excretion of calcium in the urine tends to be increased; calcium casts may form in the renal tubules; there may be cal-

TABLE V.—CLINICAL STAGES OF PRIMARY HYPERPARATHYROIDISM

Stage I	Period of Incubation	Brief history of headache and fatigue associated with hypercalcemia, hypophosphatemia and hypercalciuria. No demonstrable findings by means of roentgenograms in bones or kidneys.
Stage II	Period of Early Complications	Longer history of lassitude, fatigue, and perhaps polyuria, polydipsia, and indigestion. History of one or two bouts of renal colic. History of pains in the extremities. Possibly one spontaneous fracture. Possibly history of lamellar growth on bony parts. Roentgenograms may show osteoporosis, renal calculus or moderately well developed picture of osteitis fibrosa generalisata. Hypercalcemia, hypophosphatemia and hypercalciuria.
Stage III	Period of Advanced Complications	Long period of debility with loss of weight. Long continued history of renal colic, polyuria, and polydipsia. Roentgenograms demonstrate renal calculus and/or calculations. Long continued history of pains in extremities and over bony parts. History of lamellar growths on bony parts. Possible history of several spontaneous fractures. Skeletal deformities. Roentgenograms show widespread and extensive evidence of osteitis fibrosa generalisata. Hypocalcemia, hypophosphatemia, and hypercalciuria. Possibly albuminuria.
Stage IV	Period of Irreparable and Lethal Damage	Prolonged period of debility through many years, with loss of weight and malnutrition. Prolonged history of body pain and renal colic. Albuminuria, low fixed specific gravity in the urine, nitrogen retention in the blood with evidence of marked renal insufficiency. History of many spontaneous fractures. Skeletal deformities. Roentgenograms demonstrate extensive deposits of calcium in the kidneys with renal calculus; also skeletal deformities and widespread, extreme evidence of osteitis fibrosa generalisata. Only moderate hypercalcemia, hypophosphatemia, and hypocalcemia (due to renal failure).

cium deposits in the renal parenchyma and the formation of urinary calculi is common.

Many authors have attempted to classify the cases of primary hyperparathyroidism into clinical groups, depending for the most part upon the presence of findings in the bones or in the kidney. Such efforts seem to exaggerate the importance of prominent complications, and they do little to indicate the true nature of the disease. In our opinion it is preferable for us, as clinicians, to have a comprehensive, practical knowledge of hyperparathyroidism and its complications that will lead us early and directly to the offending adenoma. At least for the present there seem to be no good reasons to recognize clinical types. On the other hand, some advantage may come from the recognition of clinical stages in the progress of the disease, especially if such a subdivision tends to aid in the earlier identification of sufferers. An arbitrary subdivision of primary hyperparathyroidism into four clinical stages is proposed in Table V.

The differential diagnosis of primary hyperparathyroidism has been presented in many articles, such as those of Fox and Taglia (1943) and Flink (1945).

Therapy. The only effective treatment for primary hyperparathyroidism is the surgical removal of the etiologically associated parathyroid adenoma. The majority of surgeons have performed total extirpation of the adenoma in a single operation with results that have been on the whole, gratifying. Cope (1944) however recommends an occasional subtotal resection of the adenoma in the presence of extensive bone disease. This author also recommends a two stage operation for cases in which the adenoma, not discovered during the initial cervical exploration, must be sought in the mediastinum.

Roentgen therapy for the parathyroid adenoma has been ineffectual. From the structure of the

tumor this negative effect would probably accord with the judgment of most pathologists. Reports in the literature of cases benefited by roentgenotherapy include insufficient data on the calcium and phosphorus metabolism to assume that the clinical improvement may not have been due to diet alone.

Thus far the medical management of primary hyperparathyroidism has been unsatisfactory. Although a high calcium diet may influence recalcification of bones in the presence of an active adenoma, the kidney damage is likely to be accelerated by the increased intake of calcium.

Postoperative course and results from surgical management. Although no statistics are available on extensive series of cases, one obtains the impression from the literature that the immediate postoperative mortality from the removal of parathyroid adenomas has not been high. However, as many authors have pointed out (Churchill, 1936; Cope, 1941; Moehlig and Ulich, 1936) the technical and anatomical features of the operation are such that the task should be undertaken only by especially qualified surgeons. A satisfactory exploration for and the removal of a parathyroid adenoma demand knowledge, experience, and technical skill of a type not necessarily possessed by surgeons expert in dealing with diseases of the thyroid gland. It must be borne in mind that the problems of parathyroid surgery are not alone those of the regional anatomy of the neck but are specifically peculiar to the embryology, anatomy, and physiology of the parathyroid glands. The principles and technique of the surgery of the parathyroids are beautifully and thoroughly presented in articles by Churchill (1936) and Cope (1941).

In the management of cases of primary hyperparathyroidism the surgeon needs the close collaboration of an experienced internist. It is of the

utmost importance that the preoperative diagnosis be firmly established and that the surgeon be convinced of the accuracy of the diagnosis. The surgeon needs this fortification because the accuracy of diagnosis in this disease cannot be disrupted by a single exploratory operation. Furthermore, the surgeon needs this assurance for he must do a most meticulous and thorough dissection to find a small adenoma and at the same time, he must identify and carefully preserve the normal parathyroids.

Within the first few hours after the removal of the adenoma a precipitous fall in the blood serum calcium level regularly occurs therefore the danger of postoperative tetany is always imminent. Churchill and Cope (1936), Cope (1941) and Albright with his associates (1937) have demonstrated that the higher the levels of serum phosphatase preoperatively the greater the likelihood of postoperative tetany. Consequently if the preoperative phosphatase level is high postoperative tetany should be looked for and treated as soon as its premonitory symptoms appear (Flink 1945).

Many patients have noted a remarkable improvement in their subjective well being even in the immediate postoperative period. Of course the organic improvement is likely to be best in those cases in which the complications of hyperparathyroidism are least developed. In general the late postoperative results have been good, but as they are unpredictable in particular cases only a guarded prognosis can be given. Volz and Smull (1944) presented a case in which despite any evidence of the continuance or recurrence of hyperparathyroidism, there was failure of recalcification of the bones 5 years following the removal of the adenoma. Discouraging results of this type in which the bones fail to recalcify even in the face of normal serum calcium levels, may be attributed to arrested osteoclastic activity (Gutman and Parsons, 1938; Volz and Smull 1944). On the other hand, Sprunt (1938) reported a case that had a long history and extensive skeletal involvement in which there was nearly complete recalcification of the bones by the eighth postoperative month. Fortunately many cases have responded similarly well, and it is to be expected that as more patients come earlier to surgery more will obtain better results.

The parathyroid adenoma in medicine of the future. It cannot be doubted but that in the future fewer cases of parathyroid adenoma will be allowed to endure through such long periods as in the past. More cases will be recognized early in their course and will be removed before extreme

complications have developed. The shortened duration of the disease should favor the recording of more accurate and more detailed clinical histories and this will aid in fixing the time of onset. Such data will be invaluable in refining our knowledge of the growth potentialities of the adenoma. Preoperatively it is hoped that careful laboratory studies will be made repeatedly and through a long enough period so that they will throw more light upon the disturbed physiology. These studies are much needed in order that it may be decided whether a quantitative relation exists between the disturbed mineral metabolism and the size and histological structure of the tumor. Postoperatively the tumor should be accurately weighed in grams and measured in centimeters. After the gross description has been recorded and portions selected for microscopic study, the remainder of the adenoma should be subjected to bio-assay.

It is desirable that all cases of primary hyperparathyroidism be published the more complete data to be presented in the reports of the next decade will go far in answering the unsolved problems attached to this malady. Finally it should be emphasized that a thoroughgoing knowledge of the parathyroid adenoma will not only be valuable from the point of view of understanding this particular tumor but it is likely that accurate and detailed knowledge of the parathyroid adenoma may shed light upon problems connected with other endocrinologically active tumors and possibly even upon the abstruse problems of neoplasia in general.

SUMMARY

1 Surgical management of the parathyroid adenoma holds a place among the triumphs of modern surgery.

2 Operative removal of the parathyroid adenoma is the only effective treatment of this lesion and the associated primary hyperparathyroidism.

3 Historically the clinical surgery of parathyroid disease is recent and has been crowded into the brief period of the last 20 years.

4 Although the parathyroid adenoma is not a common tumor its general incidence is probably greater than is suspected.

5 During the 43 years from 1903 to 1945 reports of 322 cases of parathyroid adenoma have appeared in the literature.

6 No exact figures are available to indicate the incidence of parathyroid adenomas, either in groups of individuals or in series of surgical cases.

7 In approximately 80 per cent of the cases reported prior to 1936 the adenomas were removed

at operation and in 20 per cent they were discovered at autopsy. Better knowledge of primary hyperparathyroidism has altered these figures. In the decade from 1936 to 1945 nearly 90 per cent were removed surgically and only about 10 per cent were found at autopsy.

8. There is no evidence to support the concept that the incidence of the parathyroid adenoma is influenced by geography.

9. The exact time of origin of a parathyroid adenoma is difficult to establish; however analysis of the available data indicates that this tumor may originate at any time from childhood to old age.

10. Parathyroid adenomas have been found in each decade from the second to the eighth inclusive. For our total group the maximum incidence is in the fifth decade and 70 per cent of the adenomas were discovered in patients between 30 and 60 years of age.

11. The sex incidence of the parathyroid adenoma shows a preponderance in females over males in the ratio of approximately 3 to 1.

12. On the basis of sex there is a difference in the age distribution of parathyroid adenomas; the maximum incidence occurs a decade earlier in males than in females, and there is a qualitative difference in the age-sex distribution curves (Fig. 4).

13. Multiple adenomas were described in 20 instances, or in 6.2 per cent of the reported cases.

14. The question of multiple adenomas is discussed and the possibility of confusing supposed examples with cases of secondary hyperplasia of the glandules is pointed out. It is concluded that, up to the present time, the evidence for the existence of true multiple adenomas is meager.

15. In the great majority of cases the parathyroid adenoma is a single lesion that develops in, and therefore involves only 1 of the parathyroid glandules.

16. As the neck is entered to treat hyperparathyroidism, the first problem of the surgeon is to determine the site of the adenoma.

17. Adenomas of the parathyroid glands are about equally frequent on the right and left sides of the neck, but when the incidence of involvement of the inferior and superior glands is considered a great difference is apparent.

18. Fifty-one and six tenths per cent of the adenomas occurred on the right side and 47.4 per cent on the left side of the neck.

19. Forty-two and seven tenths per cent of the adenomas were located in the region of the right lower parathyroid; 41.1 per cent, in the region of the left lower; 9.1 per cent, in the region of the

right upper; and 7.1 per cent were located in the region of the left upper parathyroid.

20. In 10.7 per cent of the cases the adenoma was found in an aberrant position, in 63.3 per cent of this group it was in the mediastinum, in 30 per cent, within the substance of the thyroid gland, and in 6.7 per cent, it was behind the esophagus.

21. On the basis of this data on the location of the adenoma, a formula for the scientific, surgical approach to an adenoma is suggested (page 13, Table V).

22. The size of the adenoma is the second problem of the operating surgeon.

23. The weights of individual adenomas have varied through an extreme range; the smallest weighed 0.4 gm. while the largest attained a weight of 120 gm. The average weight was 12.7 gm. and the mean weight 7.0 gm.

24. For the most part the surgeon will be searching for a tumor with a weight approaching 7.0 grams, a volume approximating 4 or 5 cc., and with diameters which may vary from a mean of about 3.2 by 2.2 by 1.7 cm.

25. The smallest adenoma was more than 10 times the size of a normal parathyroid gland, while the largest adenoma was 3,500 times as large as a normal glandule.

26. By means of the blood calcium levels, it has been possible to demonstrate a roughly quantitative relationship between the size of the tumor and the degree of hyperfunction. However as the size of the adenoma increases the proportional effect of unit weight on the blood calcium becomes rapidly less and less.

27. Bio-assays of parathyroid adenomas indicate that these tumors contain a hormone that is similar to, if not identical with, that produced by the normal gland.

28. Most parathyroid adenomas are yellowish brown or reddish brown in color, moderately soft, encapsulated, and with smooth surfaces. Although some are bilobed, most of them are ellipsoidal in form.

29. Histologically the parathyroid adenoma is recognized because of its fairly typical structural pattern, but more particularly because of the presence of characteristic parathyroid cells.

30. All of the 6 types of parenchymal cytological elements found in normal glandules (Norman, 1947) may be found in adenomas of the parathyroid; these may be present in varying proportions in particular tumors.

31. An adenoma made up entirely of oxyphil cells (oxyphil adenoma) is a rare and probably special form of tumor.

32 The literature records a case in which there is reason to believe the adenoma had existed for 39 years.

33 Few patients have recognized symptoms ascribable to the adenoma for a period less than 1 year.

34 It is probable that the average duration of symptoms has been from 5 to 7 years prior to the recognition of the adenoma.

35 There is evidence to support the concepts that adenomas may exhibit a periodicity in their growth and that there are differing inherent growth tendencies in particular adenomas.

36 It appears that the incidence of parathyroid adenomas rises as the keenness of diagnostic acumen increases. During the years of the past decade more and more cases have been given the benefit of earlier surgery and fewer cases have been left to be discovered at autopsy.

37 It is recommended that confusion be avoided by confining the use of the term carcinoma to those very rare tumors of the parathyroid that exhibit indubitable evidence of their malignant nature.

38 The parathyroid adenoma is a benign endocrinologically active neoplasm which in practically all, if not in all, instances affects the bodily economy through the excess of parathyroid hormone generated by the tumor.

39 The terminal results from the action of the parathyroid hormone are well known however the exact manner in which the hormone affects these results remains a matter of conjecture.

40 The clinical disease provoked by a parathyroid adenoma is known as primary hyperparathyroidism.

41 Primary hyperparathyroidism is characterized by its insidious onset and by its cryptic chronic progression. There are no specific symptoms.

42 Few cases of primary hyperparathyroidism are recognized prior to the appearance of complications that involve either the skeletal the urinary or both of these anatomic systems.

43 The skeletal involvement in primary hyperparathyroidism (called osteitis fibrosa generalisata) is common and takes one of two forms osteitis fibrosa cystica and diffuse osteoporosis.

44 The roentgen findings of osteitis fibrosa generalisata are characteristic.

45 Osteitis fibrosa generalisata may lead to the development of deformities and spontaneous fractures, and commonly produces pain, of which the patient complains in the bones and joints.

46 Following removal of the adenoma there has been a spectacular and complete recalcifica-

tion of the bones in some cases, while in others there has been little postoperative reformation of the skeletal parts.

47 The renal complications of primary hyperparathyroidism are due to hypercalcaemia, and to the precipitation of calcium salts in the renal parenchyma or in the renal tubules and excretory passages.

48 Clinically the cases of primary hyperparathyroidism showing renal complications are likely to be less severe than those in which the osseous changes are more prominent.

49 Apparently more and more parathyroid adenomas have been discovered during recent years in urological clinics.

50 The clinical course of primary hyperparathyroidism is likely to be interrupted by such incidents as the appearance of skeletal deformities, spontaneous fractures, renal colics, and the passage of renal calculi.

51 Untreated cases of primary hyperparathyroidism progress to invalidism and death from renal insufficiency, malnutrition or other intercurrent malady.

52 Apparently no advantage is gained from the classification of cases of primary hyperparathyroidism into clinical groups.

53 It is recommended that four clinical stages of primary hyperparathyroidism be recognized (1) period of inception (2) period of early complications (3) period of advanced complications (4) period of irreparable and lethal damage.

54 The only effective treatment for primary hyperparathyroidism is the surgical removal of the etiologically associated adenoma.

55 The problems of parathyroid surgery are not alone those of the regional anatomy of the neck but are specifically peculiar to the embryology, anatomy and physiology of the parathyroid glands.

56 At least for the next decade all cases of parathyroid adenoma should be reported. To be most useful the published reports will contain accurate and detailed clinical histories and findings, repeated laboratory studies, weights and measurements of the tumor, careful histological and cytologic descriptions, and bio-assays of the adenomas.

ABSTRACTS OF CURRENT LITERATURE SURGERY OF THE HEAD AND NECK

HEAD

Bazzoli L.: The Pathology and Clinical Symptoms of the Tumors of the Salivary Glands (*Patologia clinica dei tumori delle ghiandole salivari*) Arch ital. chir. 1945 67 3

In this monograph the author reviews the gross and microscopic pathology of tumors of the salivary glands various theories of their origin their classification clinical symptoms and therapy

His own material consists of 43 cases, 34 benign and 9 malignant. After extirpation of a benign tumor the resulting fistula promptly healed following roentgen treatment. The remaining cases of benign tumors terminated in uneventful recovery.

The author believes that preoperative roentgen irradiation, improved surgical technique and the postoperative application of large doses of x rays greatly improved the prognosis of malignant tumors of the salivary glands. Surgical treatment occupies the main place in our armamentarium for the treatment of malignant tumors of the salivary glands.

JOSEPH K. NARAT, M.D.

Pricolo, V.: Bilateral Mixed Tumors of the Submaxillary Gland (*Tumore misto bilaterale della ghiandola sottomassillare*) *T. med. Milano*, 1946 3 32.

A man of 74 who had no family and no previous history of any importance reported that a month before coming to the clinic a swelling had appeared in the left maxillary region and a few days later the right submaxillary region began to swell also. The tumors increased in size until on admission the one on the left was the size of a large pear and the one on the right was considerably smaller—about the size of a pigeon's egg. The patient was in moderately good general condition.

Operation was performed in October 1944. Both tumors were encapsulated but the left one was so intimately adherent to the anterior belly of the digastric muscle that a part of the muscle had to be removed. The patient was discharged November 23, 1944 as he had been given roentgen treatment.

The tumors did not show any remnants of the salivary glands. The neighboring lymph glands were not enlarged. The histological findings in the tumors were the same. The tumor cells were massed together in the lower part and in the upper part they were connected forming cords which passed into an intercellular mucous tissue and gave the typical picture of mixed salivary gland tumor.

The different theories that have been advanced to explain the origin of these tumors are discussed. The author himself believes that the theory of inclusion

of epitheliomesenchymal rests in the glands during embryonic life and their later development under the action of some unknown stimulus is the correct one. It is the only one that explains the bilaterality of the tumors the fact that they developed at the same time on both sides and the identical histological picture on the two sides. AUBREY G. MORAN, M.D.

EYE

Gundersen T.: Observations on the Voosius Ring *Am. J. Ophth.* 1946, 29 837

Voosius who first described this ring in 1903 identified two forms—a colored one which he considered to be derived from the pars ciliaris iridis, and a more colorless one which he attributed to degenerative changes in the epithelium of the lens capsule and possibly in the anterior cortical layers of the lens.

In 1918 Hesse and Vogt showed that the ring was not an opacity in the lens or lens capsule but a thin ring of deposit on the former.

Severe trauma and intraocular hemorrhage are the most constant factors in the etiology of the Voosius ring. Hesse believes that hemorrhage is more important than trauma. Intraocular hemorrhage is one or more of these—retina, vitreous, or aqueous—was present in all 19 cases of this series. Senile and presenile eyes seem to be immune to the formation of a Voosius ring. Gundersen states that the existence of a nontraumatic Voosius ring has never been proved.

All cases in this series occurred in American soldiers between the ages of 19 and 30 years as a result of battle injury. Intraocular hemorrhage was found in every eye. Extensive vitreous or retinal hemorrhage was absent in only 4 cases. The size of the ring was constant in all cases—between 2.55 and 3.75 mm. in diameter.

Gundersen concludes that the ring does not consist of iris pigment left behind on the lens capsule as a result of an injury but that during the interchange of fluids through the anterior lens capsule, blood pigments from the aqueous are deposited in characteristic fashion.

JOSEPH ZUCKERMAN, M.D.

Vail, D.: The Scleral Resection (Eyeball Shortening) Operation. *Am. J. Ophth.*, 1946, 29 785.

The author discusses scleral resection, or the eyeball shortening operation. This procedure was introduced in 1903 by Mueller for the treatment of retinal detachment in myopia. He resected an oval piece of sclera from 8 to 10 mm. in width and from 18 to 20 mm. long from the temporal side of the eyeball. One hundred and twenty-one cases of scleral resection for detachment have been collected from the

Fig. 1. (Vall) The scleral resection operation. Diagrammatic appearance and position of the staphyloma.

literature, 25 of the retinas being successfully reattached and 31 being partially or temporarily reattached. In other words cures were obtained in about 20 per cent of the cases which is remarkably good. Lindner modified Mueller's technique in 1933. He operated 23 times on 12 eyes most of which were myopic. The best results were obtained in detachment in aphakic eyes and in those cases in which a piece of sclera from the entire circumference of the eyeball was removed in 2 stages.

Vall performed a scleral resection on an only eye which was aphakic and on which 2 previous diathermy operations had been unsuccessful. The retina was reattached and vision restored to 20/70. A scleral resection was done 3 times on the only eye of a young man who had a complete detachment but no real improvement followed.

The author reports a case of Fischel's in which de-termination brought about a cure. A young man 30

Fig. 2. (Vall) Showing the value of the fixation

Fig. 3. (Vall) Diagrammatic drawing of position of sutures.

years of age had undergone needling of congenital cataracts innumerable times. One eye was finally lost. For a retinal detachment in the aphakic eye first a Lindner undermining operation and then a diathermy coagulation were performed. At a third operation an unexpected perforation occurred. Finally at the fourth operation eyeball shortening operation of the whole lower half of the eyeball was done. A 3 mm wide crescent was removed, and this was followed by diathermy coagulation. This yielded 6/200 vision and a normal visual field which still prevails 4 years later.

It is concluded that scleral resection is feasible and offers some hope of success in detachment of the retina. It is less hazardous than removal of a clear lens in cases of high myopia.

The operation is also useful for anterior (intercalary) staphyloma and equatorial staphyloma of the sclera. The author cured a case of the latter associated with retinal detachment by excision in a manner similar to the eyeball shortening operation described by Lindner (Fig. 1). The staphyloma measured 12 by 15 mm and began 6 or 7 mm from the limbus between the tendons of the superior and lateral recti muscles. Two double armed sutures were inserted

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS CRANIAL NERVES

Lofstrom, J. E., Webster, J. E., and Schneider R. C.: The Early Pneumoencephalographic Findings following Penetrating Wounds of the Brain. *Radial* 27 1946, 47 x

In a group of 156 patients with penetrating wounds of the head treated at the 36th General Hospital, 23 pneumoencephalographic studies were performed and comprise the basis of this report. A qualitative estimate of the amount of cerebral tissue lost and the size of the calvarial defect was made and correlated with the ventricular size. Although a quantitative lateral ventricular dilatation occurred with loss of cerebral tissue and that the dilatation was usually greater in cases with extensive brain loss. In cases in which there was a large amount of brain loss there was also a dilatation of the contralateral ventricle. An interesting finding was a completely normal ventricular conformation in a case with considerable loss of cerebral tissue.

No correlation could be found—at least in the early period—between ventricular distortions and the size of the bony defect. Also it was noted that closure of the dura was apparently not an important factor.

It is postulated that the mechanism of the ventricular dilatation in these cases is on the basis of hydrodynamic compensation. As the cerebral swelling subsides the ventricles dilate as a result of the positive pressure of the cerebrospinal fluid. Although cerebral atrophy, cicatrix, and arachnoid abnormality may result in the progression of ventricular dilatation the former factors could not play an important part in these early changes during the first few months. Acute and chronic basilar meningitis with a partial block may likewise play a part in subsequent diffuse ventricular enlargement.

SPINAL CORD AND ITS COVERINGS

Pala, C.: Modularity Compression by Neurinomas in the Course of Recklinghausen's Disease (Compressioni midollari da neurinomi nel morbo di Recklinghausen). *Arch. Ital. Chir.* 945 67 175

Two cases in which Recklinghausen's disease involved the spinal cord are reported by the author. In the first case a paraplegic condition and in the second a preaplegic condition were the results of the invasion of the spinal cord. The diagnosis was confirmed in both cases by biopsy.

If the sensory and motor syndromes in the course of Recklinghausen's disease cannot be explained by the presence of peripheral neurofibromas a suspicion of the invasion of the spinal cord is justified and

myelographic studies are indicated. The results of such studies may be negative in the presence of a radicular syndrome, for which paravertebral neurinomas are responsible.
 JOSEPH K. NARAT, M.D.

PERIPHERAL NERVES

White, J. C.: Painful Injuries of the Nerves and Their Surgical Treatment. *Am. J. Surg.* 1946, 71 468.

This article considers many of the factors involved in nerve injuries. It reviews old, tried and unsatisfactory procedures used for such injuries, and presents new techniques in order to crystallize a concept of treatment for the future. Underlying pathological factors leading to painful injuries of the nerves, and as faulty regeneration, sepsis and scar formation, are noted while the theories relating to the etiology of burning pain are discussed in detail. Various types of pain including painful neuromas, causalgia, and phantom limb are discussed with regard to their etiology and the factors having a direct influence on them.

The author wishes to stress several important general facts in the treatment of the aforementioned conditions. When pain is permitted to become chronic the cerebral cortex may become so involved in its projection that no peripheral operative procedure is of value. Likewise, it is particularly important in these cases to bear in mind that any ill-advised operation will only make the patient worse. A gradual accumulation of experience since World War I has shown that the following procedures are of no value: (1) repeated resections of neuromas, (2) neurectomies or interruptions of the nerve trunks at higher levels, (3) reamputations for the relief of pain (unless the stump is poorly constructed mechanically), (4) periaxillary sympathectomy, (5) intrathecal injection of alcohol, and (6) posterior rhizotomy.

In their stead two simple procedures are advocated namely single resection of a painful neuroma, or regional sympathectomy. In the former it is suggested that the fresh nerve stump might be treated more effectively by injecting 50 per cent formalin or 1 per cent aqueous solution of gentian violet instead of alcohol. Bolder's suggestion of drawing the nerve end through a drill hole of a neighboring bone is presented, as well as Spurling's technique of covering the end of the nerve from which the neuroma has been resected, with a snugly fitting cuff of sheet tantalum. All of these are simple procedures and are theoretically sound methods which deserve careful trial but as yet the follow-up time has been too short to give an evaluation of the results.

The second operation which is discussed is regional sympathectomy either by repeated chemical block ing or by surgery. When pain is relieved during a

period of procaine block but reappears on the absorption of the drug there is a good chance that surgical sympathectomy will bring about lasting results. If there is severe pain in an injured nerve it is much better to perform this procedure after a successful procaine block, and postpone any necessary local repair until later. There is a better than even chance that the pain will be relieved and any abnormal peripheral circulation and sweating will be corrected. It is noted that occasionally the distress of painful phantom symptoms can be relieved by sympathectomy but the phantom symptom itself remains.

If these relatively simple procedures are unsuccessful the case should be reviewed by a psychiatrist before resort is made to the more mutilating operations on the central nervous system. Interruption of the lateral spinothalamic tract can relieve pain in a stump but there is some doubt as to whether the marked phantom phenomenon can be alleviated by this procedure. No relief can be expected if the pain is indelibly stamped in the cortex. As a test it appears that spinal anesthesia offers the best chance of ruling out pain of central origin after injury to the lower extremity while procaine block can accomplish the same in the case of arm pain.

If pain is definitely of central origin associated with phantom symptoms, extirpation of the post-central convolution may be attempted. Or as the procedure of final choice a frontal leucotomy may be performed for elimination of the patient's introspection developed as a result of prolonged intractable pain. Both of the latter operations are still purely experimental and prolonged research is necessary prior to an accurate assessment of their value.

The author presents 27 service cases from the United States Naval Hospitals at Chelsea and St. Albans, and 13 civilian cases from the Massachusetts General Hospital, Boston, to demonstrate the results of the procedures which he has discussed.

RICHARD C. SCHNEIDER, M.D.

Sonderland, S.: Course and Rate of Regeneration of Motor Fibers following Lesions of the Radial Nerve. *Arch. Near Psychiat. Chic.* 1946 56 133

As a result of observations on 63 cases of lesions of the radial nerve in a series of 301 consecutive cases of peripheral nerve injuries studied at the One Hundred and Fifteenth Australian General Hospital and the Repatriation Clinic, Melbourne, Australia, the author presents his views on the course and rate of regeneration of motor fibers following complete interruption of conduction in the nerve. Actually only 31 cases met his criteria.

In the majority of cases spontaneous regeneration proceeded either to completion or to a degree which contraindicated exploration of the nerve, and attention is called to the fact that this may account for the beneficial results often incorrectly attributed to neurolysis when the latter had been performed prematurely. When the condition of the nerve was not known and exploration was indicated satisfac-

tory suture could be performed in less than half of the cases (5). Most of the irreparable situations were gunshot wounds associated with fractures of the humerus. The material is carefully described, criteria are stated, and methods of investigation are outlined.

It is stressed that when a nerve regenerates the order of recovery of motor function is usually but not necessarily that in which the motor branches leave the nerve. The reasons for variation from this order of reinnervation are discussed. A comparison of observed and deduced pathological conditions of the nerve and the onset of recovery in muscle suggests that the appearance of the nerve at injury is a fairly reliable guide to the probable duration of the regenerative process. However this is not necessarily a guide to the condition of the individual fibers for neurapraxia may occur in apparently severe injuries and axonotmesis in nerves which appear normal.

A method of estimating the rate of regeneration of motor axons in peripheral nerves is presented and emphasis is placed on the fact that it deals only with the growth of functionally mature fibers since the criterion is the progression of return of function. The advantage of this method is that it is not necessary to have a knowledge of the level of the injury and of the delay occurring at that site prior to the onset of regeneration. In addition by selecting muscles innervated at different levels the rate of regeneration of nerve can be estimated separately over different segments and one is able to calculate the degree of variation in the rate of progression of regeneration. From the results it is concluded that the mean rate of regeneration over the proximal portions of the nerve is greater than that over the distal portions and that as the regeneration progresses it does so at a diminished rate. In a study of 3 cases of regeneration after suture, the rate in the proximal segment was 1.2 mm. per day and in the distal segment 0.6 mm. per day. In the cases of axonotmesis the mean rate was 1.0 mm. per day in the proximal segment and 0.8 mm. per day in the distal segment which indicated that as regeneration continues it tends to approach the same mean rate as in nerve suture cases. From the data included it would seem that the duration of the initial delay is a measure of the severity of the nerve injury.

The course of regeneration following the onset of recovery may be expressed in terms of the time required to innervate the entire nerve pattern as measured by onset of recovery in the first and last muscles to recover. Factors influencing the time of reinnervation are: (1) variations in linear extent of the pattern, (2) variations in severity of the injury with regard to the area of cross section of nerve involved and (3) variations in individual rates of regeneration.

In lesions of a minimal degree (axonotmesis) an initial delay of 10 weeks may be expected whereas in more severe injuries such as those after suture or those associated with fractures or other complica-

tions a delay of about 4 months may be expected. When the level of the lesion is known the time required for regenerating axons to reach the brachioradialis or extensor carpi radialis longus may be estimated at 10 mm per day.

The maximum latent period observed before spontaneous regeneration was 10 months, but this was unusual. It is suggested that by adding 12 to 23 weeks, according to the type and severity of injury and to the date of onset of recovery in the first muscle to recover it is possible to calculate the approximate time when voluntary contraction may be expected in the last muscle to be reinnervated.

RICHARD C. SCHMIDTKE, M.D.

SYMPATHETIC NERVES

De Souza Pereira, A.: Blocking of the Splanchnic Nerves and the First Lumbar Sympathetic Ganglion. *Arch Surg* 1946, 53: 33.

The author advocates blocking of the splanchnic nerves and first lumbar sympathetic ganglion for various conditions. It is considered a useful procedure in determining the possible results of contemplated operative measures directed at the sympathetic nervous system, and a means of avoiding possible operative failures.

The various methods of injection of the splanchnic nerves are discussed, and the author proposes his own method of blocking the nerve by the posterior approach. X rays, anatomical sections, and diagrammatic drawings placed upon the patient's back are used to demonstrate the location for injection.

A discussion of the clinical indications includes (1) cardiospasm, (2) visceral pain, (3) peptic ulcer, (4) paralytic ileus, (5) megacolon, (6) hypertension, and (7) postoperative condition following abdominal operations.

HOWARD A. BROWN, M.D.

MISCELLANEOUS

Turnbull, F.: Surgical Relief of Pain in Cancer. *Canad. M. Ass. J.* 1946, 55: 241.

In this short, somewhat philosophical article, the author is impressed by the necessity of stopping even in part if not wholly the pain which is the lot of the cancer patient. He admits, as any neurosurgeon will, that the problem is a very difficult one, and that this difficulty lies largely in our insufficient understanding of the various mechanisms of pain in the various pain producing lesions. He would use the term unmanageable rather than intractable in describing the pain, believing that it indicates on therapeutic problem.

Realizing the shortcomings of the most accurately performed cordotomy in certain patients, the author contends that cordotomy is, nevertheless, one of the most valuable means at hand of making comfortable many patients who would otherwise be doomed to a terminal existence of heavy debilitating sedation or agonizing pain. He also makes the wise observation that many such patients, having passed at length through the hands of several specialists, including the neurosurgeon, are best off when returned to the final care of their own family doctor.

JOSEPH M. ARON, M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Leiser C. W.: The Surgical Treatment of Funnel Chest. *Ann Surg.*, 1946 123 1003

Funnel chest which is a funnel shaped deformity of the anterior chest wall as the name implies has been recognized for many years under many names such as pectus excavatum trichterbrust and chondrosternum to name a few. Nevertheless the underlying pathological condition was not discovered nor a satisfactory operation devised until Brown demonstrated that the deformity was due to a short central tendon of the diaphragm and described a satisfactory surgical treatment. There is an extensive literature on the subject admirably reviewed by Ochsner and DeBakey which starts with an article by Baubinus written in 1594. Since Brown's article appeared Sweet has reported his experience with 2 cases. The author is now adding a series of 8 cases, the first of which was operated upon 2 years ago and the most recent, 4 months ago.

When the deformity is fully developed it is characterized by a deep conical depression of the anterior chest wall the apex of which is at the xiphoid. The sternum shows the greatest displacement. The manubrium is at approximately the normal level but from this point the sternum curves sharply backward until the xiphoid approaches the vertebral bodies. Some cases have been described in which the xiphoid was practically in contact with the bodies of the vertebrae and in the author's first case the distance separating them was only 1 cm. The apex of the depression may be in the midline but it is often to the right of it which makes an asymmetrical funnel. The ribs and costal cartilages attached to the sternum are proportionately involved in the deformity. The ribs tend to flare out laterally and to turn downward and backward at their sternal ends. This is particularly noticeable in the upper ribs and gives a barrel shape on roentgenological examination. The vertebral column is bent forward into an exaggerated dorsal curve. This with the chest deformity, produces an extreme example of the round shouldered hollow chested individual, further heightened by the fact that he is also thin and underdeveloped.

The effect of the deformity on the thoracic viscera is that of compression. The lung volume is decreased in proportion to the deformity but seldom to a critical level. The effect on the heart is proportionate to the pressure on it and not necessarily to the degree of deformity. There is frequently a systolic heart murmur considered to be functional.

Usually the depression of the sternum pushes the heart into the left hemithorax but there may be considerable displacement before the pressure affects the heart action. On the other hand, if the heart is prevented from being displaced a moderate depression of the sternum can produce limitation of the heart

action. The pressure effect is characterized by dyspnea and palpitation on exertion which may be so great that the patient is practically bedridden. Furthermore, as with other cardiac defects in infancy and childhood the nutrition is poor and the physical development retarded. In spite of this the oxygen saturation of the arterial blood appears to be normal. Often there is a psychologic feeling of inferiority—among the boys when they appear unclothed before their fellows especially when associated with physical limitations and among the girls when they appear in bathing suits or low necked gowns.

The movement of the thorax during respiration especially in the vicinity of the deformity is characteristic of paradoxical respiration. During inspiration the sternum moves backward and the entire funnel deepens while during expiration the movement is in the opposite direction. In other words the movements of the thorax are the reverse of the normal respiratory movements. The explanation of this was discovered by Brown who noted that the central tendon of the diaphragm was unusually short so that contraction of the muscle exerted a pull on the xiphoid and on the costal cartilages of the costal arch drawing them backward whereas a normal diaphragm by flattening its dome would allow the sternum and ribs to swing out and increase the volume of the chest. This pull on the sternum produces a deformity which is reversible at first i.e. in early infancy but when exerted over a long period of time it makes the deformity permanent unless corrected.

The permanent deformity is maintained also by the substernal ligament. This is a continuation of the linea alba of the abdomen up along the under surface of the sternum to the suprasternal notch. It is a dense fibrous band closely adherent to the sternum and involved in the attachment of the diaphragm to the xiphoid. In the established case this ligament can maintain the deformity even after the overlying sternum has been resected. Furthermore it seems to have an abnormal importance in dealing with the correction of the deformity.

The cause of the deformity is generally considered to be congenital and hereditary. In many cases some other member of the family can be found who has a similar funnel chest and not infrequently several members of the family show the deformity.

The symptoms and signs described are not seen in all cases of funnel chest. When they are present operative correction is indicated. Should the patient with obvious funnel chest be without symptoms nothing is to be gained by operation unless the deformity is increasing or the psychologic state suffers as a result from it. Then even in the absence of symptoms the author believes operation to be justified. The surgical treatment is of two types: the first and more simple is for the early stages of the deformity in infancy and is contrived to release the

Fig. 1 (Lester) The radical operation. The outer table of the sternum has been cut transversely just below the second rib (edge osteotomy indicated in inserts) and silver wire has been threaded through drill holes in the lower end of the sternum.

pull of the diaphragm on the sternum and costal arch, the second is designed to correct a deformity which has been established and must not only release the diaphragmatic pull, but also correct the bony deformity which has resulted from this pull.

The author then describes the operative procedure and gives a series of 8 cases with complete studies thereof. He summarizes his article by the following statements:

Funnel chest is a deformity of the sternum characterized by a funnel-shaped depression of the sternum with the apex at the xiphoid. It is caused by a short central tendon of the diaphragm which pulls backward on the xiphoid during inspiration. It may produce pressure on the heart causing palpitation, dyspnea on exertion (sometimes extreme) and chronic malnutrition and underdevelopment in infancy

when the deformity is in a reversible stage a simple operation suffices to correct it. Later when the deformity has become fixed, a much more extensive operation is necessary. Operation results in a high percentage of satisfactory results.

PAUL MERRILL, M.D.

Wade, P.: Untreated Carcinoma of the Breast. *Brit. J. Radiol.* 1946 9 472.

Twenty-seven cases of untreated carcinoma of the breast are analyzed. The survival rates of approximately 837 cases are collected from various sources. Seven hundred and fifty-seven of the cases are classed according to the age of the patients. A comparison is made between the survival rates in 177 treated advanced cases and the results of palliative treatment in 301 other cases. Factors influencing the mean duration of life are discussed. The duration of the untreated disease is not proved to have a definite relation to the age of the patient although the cases recorded show a slight increase in duration of the disease in the middle age groups. There is a wider variation in duration in the younger age groups, but the duration in the older age groups deviates less from the mean duration. Long durations, such as from 20 to 30 years, are unlikely in an age group having a normal expectation of life that is shorter than this period. The treatment of selected advanced cases increases the duration of life and raises the survival rate at all periods. Therefore, treatment enables the patients to regain a percentage of their normal expectation of life, which they would not have had were the disease to remain untreated. The later history of a group of treated and untreated patients should relate to the state of the disease at any given period, and to the duration of life compared with that of an individual of the same age but not known to be suffering from the disease.

EMIL C. ROBINSON, M.D.

Halberstaedter L., and Hochman A. Artificial Menopause and Cancer of the Breast. *J. Am. Med. Ass.* 1946 3 80.

Between May 1938 and January 1945 the authors induced artificial menopause by irradiation of the ovaries in 60 women with cancer of the breast. The tumors were classified according to Stenhal as those of Stage I—with no evidence of lymph node metastases at operation; those of Stage II—with microscopic evidence of metastases to the axillary lymph nodes without evidence of involvement of the neighboring tissues and organs; and those of Stage III—with involvement of the adjacent or distant tissues or organs.

Only 60 of 393 women with carcinoma of the breast seen during the period of study were irradiated to produce an artificial menopause. As a rule the artificial menopause was induced when metastases could be identified.

Improvement occurred in 56 per cent of the women in this series. The authors are more liberal in their use of the word improvement. They con-

under it proper to report a case as improved if there is alleviation of the symptoms whereas most authors report cases as improved if regression of the metastatic infiltration can be shown objectively.

Metastases to the bone responded particularly well to the induction of the artificial menopause improvement occurring in 69 per cent of the cases metastases to the pleura and lung reacted favorably in 50 per cent of the cases, metastases to the skin and local recurrence reacted less favorably and metastases to the lymph nodes showed little response. Brain and liver metastases showed no response.

Six of eight patients who had ovarian sterilization as a preventive measure are alive and there is no clinical evidence of metastases.

The best chances of improvement resulting from ovarian sterilization are found in those cases of cancer of the breast in which the tumor cells are euplastic and typical, the so-called adenocarcinomas. The chances of improvement are far fewer in the cases in which the cells are anaplastic and atypical the so-called carcinomas simplex.

Improvement following irradiation of the ovaries is temporary lasting from $\frac{1}{2}$ year to 2 years in the authors series. This is probably due to the fact that sterilization by irradiation or surgery does not completely stop the flow of ovarian hormones in the body.

EARL O. LATIMER, M.D.

Adair F. E. and Herrmann J. B.: The Use of Testosterone Propionate in the Treatment of Advanced Carcinoma of the Breast. *Ann Surg.*, 1946 123 1023

Many investigators have demonstrated that the administration of estrogenic hormones has produced mammary carcinoma in mice. An attempt to counteract this carcinogenic effect of estrogens by means of androgens was a logical sequence. This principle of inhibiting the activity of gonadal hormones of one sex by the administration of gonadal hormones of the opposite sex has been employed in recent years in the treatment of cancer.

Encouraging results have been obtained in the treatment of prostatic cancer by estrogens. There are, however, surprisingly few reports on the use of androgens in the treatment of human carcinoma. In 1939, Ulrich and Loser described favorable changes in patients with advanced carcinoma of the breast coincident with the administration of testosterone propionate. More recently other authors have published similar findings.

The authors report a series of 11 cases with the following summary and conclusions.

1. No toxic effects were noted in individuals with normal serum calcium levels each of whom received several thousand milligrams of testosterone propionate over a period of 3 months.

2. Four patients (one with soft part and 3 with osseous metastases) manifested remarkable improvement.

3. Evidence of improvement was the regression of the primary lesion and soft part metastases in 1 case

and an increase in calcification in areas of osseous metastasis in 3 cases.

4. Disappearance of pain coincided with the osteoblastic changes.

5. In 2 of the cases that exhibited deposition of calcium in the bone metastases there was a coincident elevation of the serum alkaline phosphatase.

6. Four patients did not respond to therapy and 3 others are still under treatment without clinical evidence of improvement. On microscopic study metastatic nodules from 2 of the latter group revealed hydropic changes.

7. One patient with an initial hypercalcemia associated with osseous metastases manifested a further rise in serum calcium associated with toxic manifestations in consequence of testosterone therapy. This emphasizes the importance of blood chemical studies in patients receiving this treatment.

8. We believe that testosterone propionate in large doses may in certain instances exert a favorable influence on advanced carcinoma of the female breast.

9. The number of cases studied is too small to gauge the frequency of this favorable reaction. From our limited experience the beneficial effects are unpredictable and uncertain. Likewise the duration of the favorable response and the amount of testosterone propionate necessary to maintain this improved status is as yet unknown. PAUL MERRILL, M.D.

TRACHEA, LUNGS, AND PLEURA

West J. P.: Chest Wounds in Battle Casualties. *Ann Surg.* 1946 123 936

The author's report deals with 206 battle wounds involving a thoracic cavity. The wounds of the chest cavity are classified under four headings and are discussed separately.

Eighty-seven penetrating wounds of the chest did not require thoracotomy. These patients had relatively minor wounds involving the chest cavity and received no treatment other than aspiration and debridement of the chest wall wounds. Three of these patients had a hemothorax. There was one death in the group—that of a soldier admitted to the hospital with a clostridial infection in a compound fracture of the arm. Death was thought to be caused by the toxemia of the clostridial infection although autopsy revealed extensive intrapleural hemorrhage. Forty-six patients were admitted with penetrating wounds and required thoracotomy. Thirty-five patients were admitted with sucking wounds of the chest and 38 patients had a combined thoraco-abdominal wound.

There were 17 deaths in the entire series and the author comments upon the results as follows.

Of the 87 patients with penetrating wounds not requiring thoracotomy there was only 1 death, a mortality of 1.1 per cent. Of the 46 patients with penetrating wounds requiring thoracotomy there were 4 deaths a mortality of 8.7 per cent. Of the 35 patients with sucking wounds, there were 4 deaths a mortality of 11.4 per cent. Of the 38 patients with thoraco-

pull of the diaphragm on the sternum and costal arch, the second is designed to correct a deformity which has been established and must not only release the diaphragmatic pull, but also correct the bony deformity which has resulted from this pull.

The author then describes the operative procedure and gives a series of 8 cases with complete studies thereof. He summarizes his article by the following statements:

Funnel chest is a deformity of the sternum characterized by a funnel-shaped depression of the sternum with the apex at the xiphoid. It is caused by a short central tendon of the diaphragm which pulls backward on the xiphoid during inspiration. It may produce pressure on the heart causing palpitation, dyspnea on exertion (sometimes extreme) and chronic malnutrition and underdevelopment. In infancy

when the deformity is in a reversible stage a simple operation suffices to correct it. Later when the deformity has become fixed, a much more extensive operation is necessary. Operation results in a high percentage of satisfactory results.

PAUL MERRILL, M.D.

Wade, P.: Untreated Carcinoma of the Breast. *Brit. J. Radiol.* 1946 19: 172

Twenty-seven cases of untreated carcinoma of the breast are analyzed. The survival rates of approximately 837 cases are collected from various sources. Seven hundred and fifty-seven of the cases are classed according to the age of the patients. A comparison is made between the survival rates in 177 treated advanced cases and the results of palliative treatment in 301 other cases. Factors influencing the mean duration of life are discussed. The duration of the untreated disease is not proved to have a definite relation to the age of the patient, although the cases recorded show a slight increase in duration of the disease in the middle age groups. There is a wider variation in duration in the younger age groups, but the duration in the older age groups deviates less from the mean duration. TRACHEA LUNGS AND PLEURA

West, J. P. Chest Wounds in Battle Casualties. *Ann. Surg.* 1946 123 986.

The author's report deals with 206 battle wounds involving a thoracic cavity. The wounds of the chest cavity are classified under four headings and are discussed separately.

Eighty-seven penetrating wounds of the chest did not require thoracotomy. These patients had relatively minor wounds involving the chest cavity and received no treatment other than aspiration and debridement of the chest wall wounds. Three of these patients had a hemopneumothorax. There was one death in the group—that of a soldier admitted to the hospital with a clostridial infection in a compound fracture of the arm. Death was thought to be caused by the toxemia of the clostridial infection although autopsy revealed extensive intrapulmonary hemorrhage. Forty-six patients were admitted with penetrating wounds and required thoracotomy. Thirty-five patients were admitted with sucking wounds of the chest and 38 patients had a combined thoraco-abdominal wound.

There were 17 deaths in the entire series and the author comments upon the results as follows.

Of the 87 patients with penetrating wounds not requiring thoracotomy there was only 1 death, a mortality of 1.1 per cent. Of the 46 patients with penetrating wounds requiring thoracotomy there were 4 deaths a mortality of 8.7 per cent. Of the 35 patients with sucking wounds, there were 4 deaths a mortality of 11.4 per cent. Of the 38 patients with thoraco-

abdominal wounds, 8 died, a mortality of 81 per cent. It will be observed that the total mortality in this series is approximately half that of the previous series.

In the two series combined, there is a total of 361 thoracic cases, which represents 3.6 per cent of the 10,700 battle casualties treated in the Second Evacuation Hospital between July 1, 1944 and March 1, 1945. The total mortality for the combined series of 361 cases was 43, or 11.5 per cent. Twelve patients with chest wounds who died in the shock ward before operation are not included in these figures.

The following conclusions are based upon the total experience to date:

1. Small penetrating wounds of the chest cavity are best treated by aspiration alone.

2. Penetrating wounds of the chest cavity require a limited thoracotomy (1) when the skin incision necessary for debridement of the chest wall wound causes sucking, (2) when there is extensive damage to the chest wall and roentgenographic evidence suggests severe lung damage, (3) in the presence of progressive bleeding, and (4) when large easily removable foreign bodies are present.

3. In treating sucking wounds of the chest the wound should be enlarged enough to allow suture of a laceration of the lung, removal of foreign bodies and evacuation of blood clots as well as a complete debridement of the chest wall wound.

4. In many cases thoracoabdominal wounds can be dealt with through a thoracotomy incision alone. In other cases the major injury is in the lower abdomen. These patients require celiotomy after treatment of the chest wound. PAUL MERRILL, M.D.

Samson, P. C. and Brewer L. A., III: Principles of Improving Inadequate Tracheobronchial Drainage following Trauma to the Chest. *J. Thorac. Surg.* 1946, 5: 61.

De Takats showed experimentally that thoracic wall trauma resulted in bronchial spasm and increased bronchosecretory activity. The tracheobronchial tree of patients with thoracic wounds is filled with tenacious mucous and purulent secretions. Because of the prevalence of bronchitis in soldiers under combat conditions particularly during the winter months, purulent bronchial exudate often antedates injury. Bloody or mucoid sputum which becomes purulent indicates developing infection. Fluid in the pleural cavity may give bronchial symptoms primarily especially in the presence of a bronchopleural fistula. Necrotic mucosa debris, and membranous exudate from burns of the lower airway and from the local action of certain poison gases may cause widespread tracheobronchial obstruction within a few days after injury.

Present in thoracic injuries are factors which disturb clearing of the tracheobronchial tree by effective cough. Among these are thoracic wall pain, diaphragmatic injury or paresis (reflex?) abdominal ileus, fluid in the pleural cavity and paradoxically movable chest wall from multiple rib fractures.

Signs and symptoms are easily recognizable. There is constant inefficient "wet" cough with a persistent rattling or gurgling element. Only superficial secretions are raised. Bronchial rales with a wheezing high pitched dry quality which may often be heard at the bedside are commonest. There may be sonorous rales. The patient appears to be having an asthmatic attack. Dyspnea usually means a diffuse partial bronchial obstruction with anoxia. Instant bronchial breathing changes in latency and location with a forced cough signifying patchy lobular atelectasis, which if allowed to persist, becomes pneumonia.

Röntgenograms should be taken in at least two planes. Intrapulmonary bleeding per se will not cause cardiac or mediastinal shift. Shadows are likely to be round or oval with small localized air pockets, and must be differentiated from shadows caused by atelectasis and from chest wall contusions and pleural lesions.

Important initial steps in treatment are thoracentesis, gastric and intestinal decompression, intercostal or paravertebral block and inhalations of 100 per cent carbon dioxide (rebreathing into a paper bag may be substituted). If there is continued evidence of blockage, mechanical aspiration of the tracheobronchial lumen by catheter or bronchoscopy is resorted to without delay. A simple technique for tracheal toilet with an endotracheal catheter which may be done at the bedside is discussed in detail. An unusually flaccid epiglottis is the only condition which prevents passage of the catheter and that is extremely rare.

Bronchoscopic aspiration is a more efficient procedure than catheter suction. Since it is done under direct vision, both stem bronchi will be aspirated in a more efficient manner. The use of curved suction tips allows more adequate drainage of the smaller bronchi. Further increase in the airway is provided by mucosal shrinkage with pontocaine (or cocaine) and epinephrine. The sicker the patient the more immediate is the necessity for bronchoscopy and it is mandatory if an unconscious patient has aspirated vomitus.

In conclusion the authors state that (1) bronchial obstruction may be present in patients with chest injuries as a result of retained fluid substances in the pulmonary tree, and (2) that persistent bronchial obstruction is an important factor in the development of pulmonary atelectasis and pneumonia following thoracic trauma.

The principles of improving inadequate tracheobronchial drainage are discussed. Illustrative cases are presented. LYNN JOHNSON, M.D.

Berg, S.: Combined Intrapleural and Extrapleural Pneumothorax (Pneumothorax Mixte). *Acta med. scand.*, 1946, Suppl. 170, p. 403.

Following the introduction of cauterization of adhesions according to the Jacobaeus method it became possible to extend the limits of pneumothorax treatment and achieve an effective collapse of the lung in

Fig. 1

Fig. 1 (Berg) Incomplete pneumothorax with adherent apex. 1. Pleura visceralis. 2. Pleura parietalis. 3. Extra-pleural layer of tissue.

Fig. 2 (Berg) Intrapleural and extrapleural pneumothorax. Apex part detached below the lower limit of adhesion. A horizontal part of the pleura parietalis distended

Fig. 2

Fig. 3

between the upper part of the lung and chest wall.

Fig. 3 (Berg) Combined extrapleural and intrapleural pneumothorax, ("Pneumothorax mixte") Pleura cut through right round. Combined pneumothorax cavity established. Pleura parietalis covers apex region.

cases in which it would otherwise not have been feasible. In a number of cases, however the desired effect of the collapse is not obtained because of the existence of adhesions which cannot be removed by means of intrathoracic cauterization. This is particularly the case in the presence of extensive adhesions in the apex region.

The author reports 5 cases in which following a rib resection, the adherent part of the lung was freed by separation of the tissue lateral to the parietal pleura and cutting of the detached parietal pleura which created a combined intrapleural and extrapleural pneumothorax, a pneumothorax mixte. The procedure is best explained by the accompanying schematic pictures.

SAMUEL KAHN M.D.

Lata, G. A. Latent Bronchial Carcinomas with Initial Cerebellar Symptoms (Carcinoma bronchiale latente con sintomatologia iniziale cerebellare). *Pravda med. argent.* 1946 33 1232

Bronchial carcinoma may cause nervous symptoms either from pressure on various nerves or from metastases in the brain. Metastases of bronchial carcinomas are very frequent in the cerebrum. It is said that of every 9 tumors of the brain 1 is metastatic and that 38 per cent of these metastases are from bronchial carcinomas. This is true to such an extent that at the Mayo Clinic a roentgenogram of the cranium is made at once in every case of tumor of the brain.

Nevertheless metastases of bronchial carcinomas to the cerebellum are rare. It is still rarer for them to

occur without metastases elsewhere in the brain and for them to cause symptoms while the bronchial carcinomas are still latent symptomatically, although the latter finding is not extremely unusual in metastases in the cerebrum.

Such a case of cerebellar metastasis with cerebellar symptoms preceding pulmonary symptoms is described in a man of 49. Three months before admission to the hospital his gait became unstable and after about a month he presented dizziness, headache, nausea and vomiting. He was finally obliged to go to bed and on admission to the hospital he showed mental confusion in addition to the above symptoms. He had lost 8 kgm in weight. He showed a tendency to fall to the left. Romberg's sign was negative. There were no respiratory symptoms. Lumbar puncture could not be performed on account of calcification of the vertebral ligaments. Cisternal puncture showed increased pressure of the spinal fluid. The symptoms indicated tumor of the left cerebellum and a roentgenogram of the thorax showed great enlargement of the hilar shadow to the right.

Later roentgenograms very plainly showed a tumor of the posterior part of the right lower lobe. A diagnosis was made of metastatic cerebellar tumor associated with the bronchial tumor on the right side. A decompressive operation was performed with some relief of the brain symptoms but the patient died after a period of about 2 months of acute bronchopneumonia and cachexia.

AUDREY G. MORGAN M.D.

HEART AND PERICARDIUM

Harken, D. E. and Williams, A. C.: Foreign Bodies In and in Relation to, the Thoracic Blood Vessels and the Heart Migratory Foreign Bodies within the Blood Vascular System. *Am. J. Surg.* 1946 75 80

Three cases of migratory foreign bodies successfully removed from intrathoracic blood vessels, and the salient aspects of the surgical technique employed are reported in this article. Each of the patients was wounded in battle: the first in the intracavicular region by a .30 caliber machine gun bullet. On thoracotomy the bullet was palpated in the left pulmonary artery but it became dislodged accidentally. Subsequently it was found in the right pulmonary artery at a second operation. A schematic drawing illustrated the probable migration of the bullet.

The second patient received a shell fragment in the right upper mediastinum. At operation the fragment was discovered in the upper portion of the innominate artery. The artery was completely intact. As to the course taken by the missile, it was suggested that it entered the right side of the chest and the pulmonary vein, or the left side of the heart then carried into the aorta and thence to the innominate artery where it lodged.

The third patient was struck in the right axilla at the level of the fifth rib by a machine gun bullet. At operation the bullet was found to lie in an abscess cavity anterior to and including the anterior surface of the lower branch of the left pulmonary artery. On removal a full arterial stream issued from the defect. Débridement of the cavity and repair of the artery resulted in complete recovery. It was thought that the bullet must have entered the circulation through the liver then entered the inferior vena cava, the right auricle, right ventricle and left the heart by way of the pulmonary artery.

Four cardinal indications for removing intravascular foreign bodies are presented: (1) to avoid the hazards of vascular occlusion; (2) to diminish the dangers of sepsis (local and systemic); (3) to prevent erosion and hemorrhage; and (4) to remove the possibility of embolism. Each of the 3 cases reported had one or the other of these indications for surgical intervention.

STEFEN A. ZIEGLER, M.D.

Gross, R. E.: Technical Considerations in Surgical Therapy for Coarctation of the Aorta. *Surgery* 1946, 20 1

Coarctation of the aorta is a congenital abnormality which can be corrected by direct surgical attack on the lesion. The narrowed or completely obstructed segment can be excised, and the remaining portions of the aorta can be brought together by an end-to-end anastomosis. Gross discusses the technical considerations in surgical correction for coarctation of the aorta in 5 patients so treated.

For anesthesia, the author prefers cyclopropane, administered through a tightly fitting face mask. A

vein cannula in an ankle vein is used to permit the administration of fluids and blood during and after the operative procedure.

The surgical approach is made through the posterior thoracic wall by means of a liberal incision. The aorta is exposed by a longitudinal incision of the overlying parietal pleura from the midthoracic area up over the aortic arch and over the left subclavian artery. This permits the narrowed portion of the artery to be readily seen and palpated. Severing of the vessels to free the aorta from the surrounding structures is done cautiously, and when the pericardium arteriosum is cut a high degree of mobility is gained for the aortic segment. Within the mediastinum the left vagus nerve and the recurrent laryngeal nerve are to be kept in mind and constantly avoided. A revamped Mayo-Ryan straight intestinal clamp without rubbers is employed for clamping the aorta. This instrument accommodates vessels of various sizes; it cannot slip sideways and permits considerable pressure with very little crushing effect. Silk constitutes the suture material and the aortic anastomosis is accomplished as far as possible by means of the usual type of Carrel stitch. It cannot, however, be relied upon uniformly; therefore a continuous mattress type of stitch including all layers, bringing intima to intima, and turning the vessel ends outward is employed.

The prevention of cardiac collapse is accomplished by (1) removing the remaining (upper) aortic clamp gradually over a period of 5 or 6 minutes so that the rush of blood into the lower aortic segment is somewhat retarded; (2) tipping the patient into a mild Trendelenburg position to facilitate the return of blood to the heart; and (3) quickly injecting from 150 to 250 c.c. of blood (under pressure) into the ankle vein cannula to augment the circulating fluid.

The chest is closed carefully, care being taken to avoid bleeding into the pleural cavity. The wound usually heals per primam. By removing segments of the ribs so that the ends of the bone cannot touch, postoperative pain can be kept at a minimum and sedation markedly reduced. Postoperative accumulation of fluid in the pleural cavity is aspirated as required.

STEFEN A. ZIEGLER, M.D.

Faureux, M., and Swenson, O.: Pericardomyectomy in Abolishing Anginal Pain in Coronary Disease: An Experimental Evaluation. *Arch. Surg.* 1946, 53 269.

It is generally believed that the nerve fibers carrying pain impulses from the heart and coronary vessels follow the course of the coronary vessels. They are concentrated for the most part around these vessels, forming a loose spiral network, and converge around the origins of the coronary arteries before passing over to plexuses located between the pulmonary artery and aorta, and on the surface of the aorta.pressor and depressor fibers are present in the plexus between the pulmonary artery and aorta. It is important to interrupt the pain fibers as near the heart as possible, not only for the essential reason

of not missing any but also for the reason of avoiding severance of important nerve branches to the lungs which is not without serious risks

The objectives of surgery in the therapy of coronary disease are the improvement of coronary circulation, blockade of vasomotor reactions, and the eradication of anginal pain. The operations of cervical and dorsal sympathectomy interrupt some pain pathways but it has not been proved that all pathways have been cut nor that circulation improves. Clinical experience has borne out this belief.

Investigation has shown experimentally and clinically that venous ligation aids in opening and dilating the arterial anastomoses of the extremities. This view is tenable in the case of the coronary circulation also as evidenced by the studies following coronary venous ligation.

With these thoughts in mind the operation of pericoronary neurectomy was devised. If it would block reflexes then it should abolish anginal pain. Experimental work on the dog showed that in controls there was 20 per cent survival after ligation of the circumflex artery. In a group of dogs prepared by coronary venous ligation, there was 50 per cent survival after ligation of the artery. In a third group prepared by pericoronary neurectomy alone the survival rate was 60 per cent after arterial ligation. In a fourth group prepared by pericoronary neurectomy and coronary venous ligation, the survival rate was shown to be 86 per cent following ligation of the artery.

The conclusions drawn were that coronary venous ligation helps to open and dilate the coronary anastomoses and that pericoronary neurectomy blocks reflexes, thus aiding in the prevention of ventricular fibrillation and rapid death. The unsolved problem in these studies was the extent to which the operation could diminish pain in coronary disease.

The experimental method for the study of cardiac pain, which has become fairly well standardized was devised by Sinton and Leth. This method was applied to a control group of dogs which reacted as postulated. It was also applied to a group of 10 dogs prepared in advance by pericoronary neurectomy. Of this group 6 gave no response, 1 gave no response on five occlusions and a questionable response on another 2 were doubtful, and 1 had a positive reaction graded one plus. One dog in the series developed a ventricular tachycardia on the first occlusion with no evidence of pain. It is interesting to note that these attacks are often followed by ventricular fibrillation in the intact dog.

Two patients who have submitted to the operation of pericoronary neurectomy combined with ligation of the great cardiac vein, have been under observation for more than a year. Seven others who have been operated upon more recently are under observation. The clinical results are in accord with the experimental findings. As yet no final judgment can be reached regarding the procedure but there seems to be enough justification for further clinical trial.

EDWIN W. PASSARELLI, M.D.

SURGERY OF THE ABDOMEN

GASTROINTESTINAL TRACT

Kalliser R.: Nutritional Abdominal Allergy from a Surgical Standpoint (Ueber eine nutritive abdominale allergie vom standpunkt des chirurgen) *Acta chir scandinav.* 1946, 94 Supp. 3

The first 118 pages of this work are concerned with a review and evaluation of the literature of the general subject of allergy in an attempt to establish some norms in the universal conflict of experiences and opinions.

Particular attention has been allotted to the consideration of the subject of allergy in the special surgical subjects of gastric and duodenal ulcer of diseases of the bile passages, of appendicitis and of a few other disease pictures of surgical interest in the realm of abdominal allergy. The remaining 206 pages are taken up with the author's clinical and histopathological studies of the role played by allergy in these same surgical conditions.

The various methods of study considered in the first part such as the Prausnitz-Kuestner test, the matter of food antipathies, the exposure of the patient to the suspected food entities or food categories and the withholding of these factors, and the leucopenic index, are given but brief attention, almost exclusive study being made of the skin tests. The histopathological part is concerned with the occurrence and significance of the local tissue eosinophilia in cases of ulcer, cholecystitis, and appendicitis.

The material consisted of 705 patients, of which 93 (68 males, 24 females) presented cases of gastric or duodenal ulcer, 86 (10 males, 76 females) disease of the bile passages, 159 (88 males, 71 females) appendicitis, and 310 (146 males, 164 females) various forms of abdominal distress of undetermined nature. The control material consisted of 83 patients (69 males, 14 females) who were not suffering from any of the cited surgical abdominal conditions and were not presumed to be affected by allergic disease. The cutaneous tests were made on the upper part of the back. They were chiefly intracutaneous and were at first conducted with the extracts of Parke-Davis and Co. and later with the extracts prepared by Frugoni after the method of K. Hansen of Luebeck.

From his studies the author considers that food allergy is not of material significance in the pathogenesis of gastric or duodenal ulcer, the tissue eosinophilia probably resulting from local changes in the ulcer. However, some cases of gastritis with local eosinophilia may be the result of food allergy. As regards the bile passages, food allergy may cause acute biliary colic or induce certain abdominal symptoms which remain after cholecystectomy, however, such conditions are not believed to play any great part in the causation of bile tract disease. Here again

the local eosinophilia of the gall bladder is assumed to be merely an aspect in the normal development of the cholecystitis, or it may be an expression of an allergy which in a few cases might cause a special, less acute type of cholecystic inflammatory reaction. In appendicitis the eosinophilia observed in the mucosa, or even that type of local infiltration permeating the entire wall of this organ, is interpreted to be of about the same significance as that observed in the case of gall bladder disease. Finally, in the group of less well characterized abdominal symptoms, allergy is obviously one of the various etiologic factors which may be at work, however, in a large series of cases it cannot be considered as of paramount importance.

Nevertheless, in the gastrointestinal inflammations the question of allergy is of great significance, because allergy frequently gives rise to the clinical features of an acute abdominal condition. The group the author divides into 6 subgroups.

The first of these subgroups consists of those cases presenting the symptoms of disease of the urinary tract, liver or bile passages, of tuberculous lymphadenitis or peritonitis, or of intraperitoneal adhesions. Here in the author's material there was no instance of suspicion of a nutritional allergic etiology for the manifestations.

The second subgroup comprises apparentlyynecological affections, and the third comprises the cases of achylia gastrica, without any evidence of allergy.

The remaining 3 groups consist respectively of cases of gastritis, enteritis, and colitis in which the incidence of positive skin tests was somewhat greater than in the control group although not sufficient to constitute a statistically demonstrated difference. In none of these groups could allergy play a predominating role as an etiologic factor. In these patients there is usually a discrepancy between the subjective and objective manifestations. The patient complains of severe pains with little or no pain on pressure, and the defense musculature is slight or absent. The temperature is normal or but slightly elevated. It may however exceed 39 degrees. A moderate amount of leucocytosis may be present, but an eosinophilia will seldom accompany the acute attack.

Finally, the author reports an apparent instance of pancreatic irritation which seemed to have been caused by nutritional allergy, however, he does not consider it of sufficient import to have any bearing on the subject here treated. This case and a few other experiences are considered of value for further studies on the subject of nutritional allergy in surgical abdominal conditions, and the author recommends especially that attention be given to the selection and employment of more reliable allergens.

JOHN W. BLEDWAT, M.D.

Bell, H. G.: The Treatment of Cardiospasm by Esophagogastrostomy. *Surgery* 1946 20 104.

The etiology of cardiospasm is still in dispute. Comparatively few cases are reported in which an operation was performed in an attempt to relieve the condition.

Dilatation is the simplest procedure and should always be given a trial. Of the operative procedures esophagogastrostomy seems the most logical. The author reports on 10 such procedures. The results were very satisfactory; there were no deaths and 8 of the 10 patients received complete relief. Two patients required subsequent operations.

In the last 2 cases the flaplike valve action of the redundant posterior wall of the anastomosis caused the persisting symptoms. A method of correcting this in which a suture is used to anchor the posterior wall of the anastomosis to the posterior wall of the stomach is described. F. J. LESKMAN JR., M.D.

Grimson K. S., Reeves, R. J., Trent J. C., and Wilson, A. D.: The Treatment of Patients with Achalasia by Esophagogastrostomy. *Surgery* 1946, 20 94.

Progressive dysphagia and starvation occasionally necessitate surgical intervention in cases with derangement of function of the lower esophagus.

The authors report on a series of 9 cases in which an esophagogastrostomy was performed on patients with achalasia. A transabdominal approach was utilized, the esophagus was mobilized and care was taken to bring down the dilated segment of the esophagus. Incisions were made into the esophagus and fundus and an anastomosis was performed. There were no operative mortalities in the 9 cases. The cases exhibited marked improvement.

The theories of causation of the disorder are discussed. The authors believe that the esophageal

dilatation is secondary to the chronic obstruction and not idiopathic. Cases in which a sympathectomy was performed for hypertension revealed no disturbance of esophageal function. Similarly, cases in which a vagotomy for peptic ulcer was performed revealed no disturbed function. The authors believe that the myenteric plexus easily controls motility by itself and may be only partially regulated by sympathetic and parasympathetic impulses. The fundamental pathology may reside in lesions of the myenteric plexus. F. J. LESKMAN JR., M.D.

Walters, W.: Diverticula of the Stomach. *J. Am. M. Assn.*, 1946 131 954.

Five cases of diverticula of the stomach were presented. All the patients concerned had symptoms of severe dyspepsia which had led them to seek medical and surgical treatment. Two of the patients had been managed on a medical regimen for peptic ulcer prescribed elsewhere in the belief that a gastric ulcer was present in 1 case, and a duodenal ulcer in the other.

In each case roentgenological examination of the stomach at the Mayo Clinic revealed the presence of a diverticulum. Gastroscopic examination was performed in but 1 case; in another case it had been performed elsewhere before the patient came to the clinic. In 1 case the diverticulum was not found at the first operation but since the symptoms persisted a second operation was performed at which time the diverticulum was found and removed. Four patients were relieved of their symptoms of epigastric pain after removal of the diverticula; the diverticulum of a fifth patient was inverted and comparable relief was obtained thereby.

In all cases the diverticula extended from the posterior wall of the stomach, just off the lesser curvature. In 4 cases the surgical approach to the area

Fig. 1. (Grimson, K. S. et al.) The drawings illustrate the importance of extending the incision for esophagogastrostomy or cardioplasty through the stomach and small lower esophagus into the enlarged portion of the esophagus

to insure adequate drainage. Section, rather than the use of temporary clamps or ties about the esophagus, facilitates upward extension of the incision.

in question was made by dividing the gastrolleal ligament and the gastrocolic omentum which permitted exposure of the diverticulum by drawing the fundic end of the stomach downward and toward the midline. In 1 case the diverticulum was approached through the gastrotrophic omentum. In the fifth case, the presence of multiple blood vessels in the wall of the diverticulum, plus the inflammation present in the diverticulum as a result of the retention of food, undoubtedly accounted for the hemorrhagic episodes.

Retention of food in the diverticula undoubtedly produces gastroparesis; this plus the diverticular gastritis, accounts for the pain.

Naturel G.: Fibromas of the Stomach (Sui fibromi dello stomaco). *M. J. J. Med. T.* 1946, 31.

The author describes a case in which a true fibroma of the stomach was accidentally found at autopsy. In reviewing the literature he describes the clinical and anatomical characteristics of benign tumors of the stomach which, by their location, symptomatology and complication suggest malignancy and for this reason are usually treated surgically and radically.

Benign tumors of the stomach in contrast to the malignant ones, are rare and were considered exceptional up to some time ago. In spite of the progress in diagnosis the pathologic-anatomical literature remains scarce. In the world's literature 6 fibromas were reported in 1929, 14 in 1932, 23 in 1937, 40 in 1932 and 63 in 1941 in contrast to the notable number of myomas (386) and papillomas (316). In order of frequency the true fibromas come after the myomas, papillomas, and adenomas.

Fibromas of the stomach are interesting because of their rarity and because of their clinical symptomatology which very often simulates that of a malignant tumor and misleads the clinician, the histologist and surgeon. Diagnosis of benign tumors of the stomach is rather difficult because the clinical subjective and objective symptoms are common to other stomach affections (gastritis, ulceration, carcinoma) and only by the histological examination can we arrive at a correct diagnosis.

The author describes a case of true fibroma of the stomach found accidentally at autopsy in a patient who died from pneumonia. He gives the pathologic description and states that the tumor originated from the submucous connective tissue solely. According to the literature the fibroma of the stomach is usually rounded or oval and of a firm elastic consistency it varies in size from that of a nut to that of an adult head, the average being that of a hen's egg; it is often pedunculated. Its weight varies with its size reaching as much as 500 gm. and its surface is smooth or slightly irregular and broken which gives it a tendency to ulcerate. On section the surface is a pallid undulating bundles with connective tissue fibers. This tumor is generally found in men of middle age.

The lipoma may be differentiated by its softness and yellow color. The myxoma by its special consistency and gelatinous transparent aspect. The angiosarcoma by its richness of vessels and the sarcoma by its red berry color and scarcity of connective tissue fibers, which differentiates it from the fibromas or myomas. However the fibromatous myomatous and neurofibromatous tumors cannot be differentiated easily at operation. The tuberculous and luteic granuloma with neoplastic form cannot be differentiated at first sight from true tumors and frequently only a histological examination will lead to their correct diagnosis.

G. ALMEIDA LIMA, M.D.

Gaspar J. B., and Vidal-Colomer E.: Thread Employed as Suture Material in the Stomach and the Possible Cause of Postoperative Complications (Los hilos de sutura gástrica como posible causa de complicación postoperatoria). *Rev. Op. y Gyn.* 1946, 5, 233.

This article concerns 4 cases in which some form of surgical treatment for ulcers had been done and in which a recurrence of the subjective symptoms took place subsequently.

X-rays showed the presence of an ulcer and gastroscopic examination revealed the association of a nonabsorbable thread used as suture material in the first operation.

The patients were operated upon by different surgeons and the technique employed was different in each case. The gastroscopic appearance of the lesion and the proximity of the thread demonstrated the causal relationship beyond doubt.

STEFAN A. ZIMMER, M.D.

Blain A., III and Kennedy J. D.: The Effect of Penicillin in Experimental Intestinal Obstruction. *Ann. J. Surg. B. Minn. Hosp.* 1946, 79, 1.

In this experimental study on 20 dogs, a simple intestinal obstruction was produced by division of the ileum and closure of the ends. Strangulation of a portion of the proximal part of the ileum was produced by ligation of all the veins over a 60 cm. length of bowel and ligation of all vessels over a short segment of this portion.

All dogs received blood transfusions routinely following surgery and these were repeated as indicated by frequent hematocrit determinations. Saline solution was given in sufficient quantities to prevent hypochloremia. Gelatin solution was given if the hematocrit rose despite the administration of saline solution.

Ten of these dogs received no further treatment and survived from 16 to 35 hours. Pathologically the bowel was swollen and contained blood (unless perforation had occurred). The peritoneal cavity contained from 500 to 1,000 c.c. of a bloody transudate resembling blood serum with a hematocrit between 12 and 15. Ulceration and necrosis of the bowel wall were marked.

The other 10 dogs were treated with massive doses of penicillin in addition to the treatment outlined

above. One dog died in 26 hours while 9 were protected for 50 hours or more, and 8 for 72 hours or more. Two dogs were subjected to resection and side-to-side anastomosis after a period of 72 hours and were cured.

The bowel at autopsy in the penicillin treated group was generally thick and firm instead of friable as in the control group. Microscopically there was hemorrhage necrosis and ulceration. In some dogs some healing was seen less infection was present otherwise the findings were identical with the control group.

Careful and complete blood chemical studies were made and reported. Bacteriological studies showed that the same organisms were present as at the time of operation in both groups.

The authors conclude that penicillin in massive doses prolongs life in strangulated ileal obstructions for a limited period of time. A plea is made for anti bacterial therapy in all cases of strangulated obstructions or cases in which strangulation cannot be ruled out preoperatively but as an adjunct to and not as a substitute for early and adequate surgical procedures.

THOMAS C. DOWNES, M.D.

Bohmansson G. The Problem of Surgical Arrest of Massive Hemorrhage in Peptic Ulcer. *Acta chir scand.*, 1946, 94, 362

Widely divergent opinions are still held by the advocates of active surgical intervention on the one hand, and those who recommend expectant medical treatment on the other, in the treatment of acute hemorrhage due to peptic ulcer.

The author's observations are based on over 200 cases of hemorrhage due to ulcer which were submitted to operation during the acute stage of the hemorrhage. The author considers the factors which should be borne in mind in deciding for or against operation. After reviewing the work of Meulengracht, he believes that although the mortality was only 1 per cent, the primary material was not classified according to the severity of the hemorrhage and it is therefore not directly comparable with that in other statistical surveys.

Treatment with food, fluids and blood transfusions has considerably improved the prognosis in cases treated conservatively. A typical example is cited in the statistics from Orebro Sweden since 1939, when the benefits of this form of therapy were recognized. The percentage of cases of manifest hemorrhage treated operatively has dropped from 45 per cent to 7 per cent since that time. The choice of therapy whether operative or conservative was determined by the joint decision of both the internist and the surgeon. Although treatment by conservative methods is certainly of great value, there always remains a category of cases in which medical therapy is helpless but in which radical surgical intervention offers a chance of saving the patient's life and preventing another fatal hemorrhage. Even the devoted followers of the Meulengracht method recognize this fact.

It is generally agreed that operation should not be undertaken in cases of occult hemorrhage in cases in which manifest hemorrhage does not affect the general condition of the patient in the form of shock or severe anemia nor in those cases in which bleeding can be checked promptly by medical treatment. There are certain general or special contraindications to any form of surgery which should also be considered here. Surgery is contraindicated in conditions such as cerebral hemorrhage severe kidney disease, marked senility heart failure and so forth.

The author delineates two groups of cases in which he recommends that operation be considered in order to prevent further hemorrhage.

1 Cases in which the roentgenogram reveals a niche, in which there has been previous perforation or in which a definite diagnosis of callous ulcer has been made at an earlier date and which exhibit one of the two following characteristics: (a) serious periodical hemorrhages in the course of treatment with diet, and (b) severe anemia with continuous hemorrhage and decreasing serum protein levels.

2 Cases in which hemorrhage brings the blood levels below the shock threshold and in which it is difficult to raise the blood pressure with transfusions.

Relief from shock is the first step. This is accomplished by means of large blood transfusions lowering the head of the bed and the administration of oxygen. Protein infusions may be used when hypoproteinemia is present.

The objective of the operation is exact hemostasis resection or excision, and the prevention of further hemorrhage. Palliative operations are of no value. Surgery should be undertaken as soon as possible after shock has been treated to avoid the danger of another hemorrhage. The author uses Bilroth's I or II procedure under spinal anesthesia. Repeated blood transfusions to combat the anemia are given postoperatively. The serum protein levels and carbon dioxide level are carefully checked and the par enteral supply of fluid is gauged according to the needs of the patient. Oral feedings are instituted as soon as possible by giving strained foods with a high vitamin and high protein composition including oral amino acid preparations. The toxic effect of residual blood in the alimentary tract is counteracted by avoiding hypoproteinemia and thereby restoring the intestinal function as quickly as possible. The danger of incomplete healing along the line of suture due to edema of the intestinal wall is obviated by keeping the serum protein level within normal limits at all times.

The following succinct sentences from Bohmanson's article are worthy of quotation as a rule the internist prefers to postpone operation as long as possible while the surgeon favors operating as soon as possible. Therefore in the interest of the patient the two each knowing his own and the other's possibilities as well as limitations, should co-operate and shoulder the responsibility jointly. It would seem that the internist's objective should be not to lose any cases postoperatively because operation is done

too late, while the surgeon's aim should be to operate only in cases where there are vital indications for operation and to be able to justify his decisions against operation by autopsy material from the medical service. These objectives are difficult to attain but are well worth the effort.

The results of this program are as follows:

The total mortality for manifest hemorrhage has decreased from 9.1 per cent in 1939 to 5.1 per cent. The number of cases operated upon has decreased from 45 per cent to 7 per cent of the total. The mortality for conservatively treated cases has decreased from 6 to 5 per cent while the postoperative mortality has dropped from 13 to 5 per cent.

HAROLD LAUFMAN, M.D.

Cummins, G. M., Jr., Grossman, M. I., and Ivy, A. C. A Study of the Time of Healing of Peptic Ulcer in a Series of 69 Cases of Duodenal and Gastric Craters. *Gastroenterology* 94:6, 7 50.

The determination of "healing time" of peptic ulcer is important, in a practical sense, for the evaluation of new methods of treatment and for judgment of the efficacy of treatment in an individual case, and it is important theoretically for a comparison of the healing power of peptic ulcers in man and in lower animals. A review of the literature reveals that accurate data on the rate of healing are not available. The healing time judged by the time of disappearance of the crater radiologically as was done in this series, has its limitations of interpretation. The data on the estimation of the healing time for a series of 63 duodenal and 6 gastric craters are presented. The average "healing time" for the former group was 37 days and for the latter 48 days, by x ray. The treatment time of x ray examinations and roentgen studies were standardized as much as possible. A comparison was made of the estimation of healing time by x ray and gastroscopy in gastric craters. No correlation was found between the healing time and the size of the crater, age of the patient, recurrence, or the duration of symptoms.

Chronic duodenal or gastric ulcers in man usually heal rapidly under conditions of strict medical management. This observation is of great significance in the light of experimental observations on animals, and its implications have hitherto been unrecognized. When the healing time of an experimental excision ulcer of the pyloric or duodenal mucosa of the dog is compared with the usual rate of filling of a crater of a duodenal or gastric ulcer in man under strict medical management, the difference is not striking. Similarly the healing time of an excision ulcer of the stomach of the rabbit on rough food is comparable to the filling time of the crater of a gastric ulcer in man. There are actually only two differences between the healing of an excision ulcer in the dog and the healing of a "chronic" peptic ulcer in man. One is that in most ulcer patients favorable conditions are required for prompt healing, the second is that in some ulcer patients the lesion heals very slowly and occasionally perforates or erodes a

blood vessel even under favorable conditions. These two factors are related to the striking tendency of peptic ulcer in man to recur after it has healed.

CHARLES RAYOR, M.D.

Shapiro, A. L. and Robillard G. L.: Morphology and Variations of the Duodenal Vasculature; Relationship to the Problems of Leakage from a Postgastrostomy Duodenal Stump, Bleeding Peptic Ulcer and Injury to the Common Duct. *Arch. Surg.* 94:6, 5 571.

After a rather complete review of the literature on methods of closure of the duodenal stump in gastrectomy or pylorotomy, the authors conclude that the most prevalent complication is leakage of the stump. This complication is believed to account for the largest part of the mortality ranging from 8 to 30 per cent, which is reported for this operation. It is noted that the recent literature on techniques of duodenal mobilization prior to closure stresses the necessity of adequate freeing of the duodenum from the pancreas. The authors found only two brief comments on the possibility that this procedure might devascularize the duodenal stump and thus defeat the purpose for which the technique was designed.

In addition to reviewing the descriptive literature on the anatomy of the duodenal vasculature, the authors dissected 62 bodies. The gastroduodenal artery was present in 70 per cent of the specimens but was of small size. This vessel is practically always ligated in the course of gastrectomy. In 75 per cent of the cases the large anastomotic arcade between the superior and inferior pancreaticoduodenal vessels representing a connection of the celiac axis

Fig. 1. The peripancreatic pancreaticoduodenal arterial arcade. This was present in about 75 per cent of the cases. G.D.A. indicates the gastroduodenal artery; R.G.E.A. the right gastroepiploic artery; P.P.D.A., the posterior pancreaticoduodenal artery; A.P.D.A., the anterior pancreaticoduodenal artery; I.P.D.A., the inferior pancreaticoduodenal artery; S.M.A., the superior mesenteric artery; A.V.R., the anterior vasa recta, and P.V.R., the posterior vasa recta.

Fig. 2. Common variants in pancreaticoduodenal arterial circulation. Left, Anterior arcade partly complete, with inferior pancreaticoduodenal and postero pancreatic arteries branching (present in about 15 per cent of the cases). Right, Mesenteric arcade and branching pattern (present to some extent in 10 per cent of the cases). G.D.A. indicates the gastroduodenal artery. A.S.P.D.A., the anterior superior pancreaticoduodenal artery. P.S.P.D.A., the posterior superior pancreaticoduodenal artery. R.G.E.A., the right gastroepiploic artery. I.P.D.A.A., the inferior pancreaticoduodenal artery and S.M.A. the superior mesenteric artery.

Fig. 3. Variations in configuration of the vasa recta at the region of the duodenal stump. A, Usual pattern. B, Widely spaced "blow-out" pattern. C, Devascularization of the duodenal segment by avulsion of the ramal duodenales in separation of the duodenum from the head of the pancreas. D, Extent of devascularized duodenal stump susceptible to ischemic necrosis resulting in many commonly adopted procedures for gastrectomy.

with the superior mesenteric artery was present (Fig. 1). In 35 per cent of the specimens a complete arcade was absent. In 15 per cent the superior pancreaticoduodenal vessels were well represented but large connections with the inferior pancreaticoduodenal vessels were lacking (Fig. 2 left). In 10 per cent neither the superior nor the inferior pancreaticoduodenal vessels were well developed and the anastomosis was even less prominent (Fig. 2 right). Anomalies were noted in the origin of the pancreaticoduodenal vessels and were carefully described

The configuration of the vasa recta of the region of the duodenal stump is described and well illustrated (Fig. 3) to show the effect of ligation of these end arteries during mobilization of the duodenal stump.

The arterial supply of the common bile duct was carefully worked out and illustrated. Injuries to these end vessels might well result in localized ischemic necrosis and later unexpected stricture or fistula.

The necessity for minimal surface exposure

Fig. 4. Schematic cross section of the duodenum and vasa recta, demonstrating the end artery character of the vasa recta. This indicates the absence of major marginal or intramural anastomotic branches.

Fig. 5. Nonfilling of ligated vasa recta of the duodenum on injection of cannulated adjacent arcades and vasa recta. Experimental demonstration of the end artery character of the vasa recta. Left, Longitudinal segment. Right, Cross section.

In operations on this structure is stressed. The circulation of the pancreas is briefly reviewed.

The utility of ligation for the control of hemorrhage from a duodenal ulcer is demonstrated by an illustration which shows that such a procedure is tantamount to complete devascularization of the duodenum and head of the pancreas.

The vasa recta of the duodenum were injected with India ink to show their character as end arteries and the lack of intramural or marginal anastomoses (Figs. 4 and 5). This finding agrees with that of other workers on this subject.

The literature on the safety factor in mesenteric ligation is reviewed.

In conclusion the authors point out the similarity between the incidence of poor anastomosis of the duodenal vessels and that of duodenal leakage. In version of the freed duodenum to the point of pancreatic attachment so that intact vasa recta may provide an intact intestinal circulation is suggested.

THOMAS C. DOUGLASS, M.D.

Cave, W. H.: Duodenal Injuries. *Am. J. Surg.* 1944, 74: 26.

The author reports 118 cases of duodenal injury with a mortality of 55.9 per cent in the first 10 days. The site of the wound of entry was fairly consistent, the missile entering the right side of the trunk, either front or back, in 85 per cent of the cases. The patients who died were in a more severe state of shock upon entry than those who recovered. In more than half of the deaths shock and hemorrhage were the recorded causes of death. Two fatalities resulted from peritonitis due to injuries overlooked at operation, one resulted from a laceration of the common duct and the other from a perforation of the third portion of the duodenum. An important finding was the factor of multiple complicating lesions, such as usually the case in duodenal injuries. In only 3 cases did the damage involve the duodenum alone. It was shown that the mortality was doubled in the presence of 3 complicating injuries and tripled in the presence of 4. In 9 cases there was laceration of the vena cava with 8 deaths. There were 3 cases of portal vein laceration, 3 of laceration of the pancreaticoduodenal artery and 1 each of laceration of the hepatic and right spermatic artery. All of these cases terminated fatally.

There is a fairly constant wound pattern when the duodenum is injured. For example, if it is a wound of the right upper quadrant that has involved the right kidney, liver and right colon, injury to the duodenum is quite likely. Pancreatic injury or marked features in 1 case, both at operation and necropsy. The gall bladder was injured in 17 cases, and cholecystectomy was necessary in 8. Fifteen patients had associated chest injuries. Damage to the blood supply of the right side of the colon was not an infrequent finding in this series; right colectomy was required in 3 cases.

After repair of the laceration or transection of the duodenum, the site of repair was drained in most of the cases and the peritoneum was closed over the wound. Two duodenal fistulas developed, both occurred in cases of transection of the duodenum with end-to-end anastomosis.

It is obvious from this report that duodenal injuries carry a high mortality and too much stress cannot be placed upon the advisability of thorough exploration of the duodenum in cases in which there is any possibility that the missile has perforated the retroperitoneal space behind the right colon. A curative exploration can be done only by reflecting the right colon.

HAROLD LUTTMAN, M.D.

Fallis, L. S., and Warren, K. W.: The Surgical Treatment of Jejunal Ulcer. *Am. J. Surg.* 1944, 74: 4.

Some 15 per cent of the patients undergoing gastroenterostomy develop jejunal ulceration. All of the jejunal ulcers appear opposite the stomach or in the efferent loop. A patient who suffers a rupture of a postoperative jejunal ulcer will have had, in many

stances a former perforation of a gastroduodenal lesion. It would appear that some patients exhibit not only an ulcer forming diathesis but equally important a perforative tendency. The serious complications of jejunal ulcer are hemorrhage free perforation and gastrojejuno-colic fistula.

Intensive medical therapy is tried in almost every instance of jejunal ulceration but the response is generally poor and most of the victims are subjected to surgery without undue delay. In addition to the usual preoperative preparation for gastric resection it is important to cleanse the colon thoroughly because the jejunal ulcer may be adherent to the colon and this organ may have to be opened in the course of the operation.

The authors technique consists in detaching the transverse mesocolon from the anastomotic area and then resecting the involved portion of jejunum containing both the anastomotic site and the ulcerated area with its adjacent mesentery. If the previous operation has been a gastroenterostomy subtotal gastric resection is then performed in the usual manner. Isoperistaltic retrocolic terminolateral gastrojejunostomy is then completed with the anastomosis lying distal to the restored jejunum. Peritoneal soiling is limited by using a closed technique.

HUROL LUTKEN, M.D.

Bray, E.: Invagination of the Haustra of the Cecum (Le invaginazioni delle haustra del cieco) *Minerva med. Tor.*, 1946 2 213

The author cites and describes 6 cases of invagination of the haustra of the cecum—the highest number of cases coming under the observation of one man—in the period from 1940 to 1945. Research into the records revealed only 40 cases published up to the present time. The author states that this morbid form apparently escapes the clinical diagnosis being frequently mistaken for acute appendicitis and that at operation the rarity of the affection is more apparent than real. He describes the clinical data that may suggest invagination of the haustra and advises that the examiner should keep the condition in mind to avoid its being unrecognized during surgical intervention.

The affection is relatively rare and must be recognized by the examiner. The author cites 6 cases under his observation admitted as acute appendicitis in which invagination of the cecal haustra was found at operation; the appendix was relatively normal or secondarily involved in edematous pathology.

Various predisposing causes for this condition were given: mobile cecum, ulcerations foreign bodies, the presence of oxyuris inflammations and circumscribed spasms; modifications of intestinal peristalsis caused by a parietal lesion or the beginning of more progressive invaginations.

The symptomatology has few characteristic elements and usually causes the cases to be referred to the surgeon as acute appendicitis. The onset is often marked with cramplike pain at times becoming continuous and referred to the epigastric perium-

bilical zone or right lower quadrant. Vomiting is not constant. The temperature is normal or slightly elevated. The pulse is usually good. The abdomen is generally soft or one may find a certain resistance in the right lower quadrant. Presure elicits pain at McBurney's point or a bit higher and one may at times palpate a more or less defined and tender mass.

As a rule the surgeon does not make a preoperative diagnosis but he may suspect the condition clinically by the rapid appearance in the iliocecal region of a tumefaction of doughy consistency, which is painful and tender to pressure accompanied by cramplike pain but no fever.

At operation if the parietal peritoneum appears more edematous than red if a bloody serous discharge is encountered and if the cecal wall is edematous the surgeon is cautioned to expose the cecum and search for its invagination.

At times the roentgenological examination may be of value. The diagnosis is based on a defect in the filling of the cecal wall at the expense of one or more haustra usually on the external cecal border.

G ABRAHAM LIVA, M.D.

Kay J H and Lockwood J S: Experimental Appendical Peritonitis. The Prognostic Significance of Certain Hematological Factors, Especially the Prothrombin Time. *Surgery* 1945 50 36

Although there has been a definite reduction in the mortality from appendicitis since the introduction of new chemotherapeutic agents there has remained considerable uncertainty as to whether the apparent reduction is due to chemotherapy or to improvements in ancillary methods of treatment, such as maintenance of fluid electrolyte and blood requirements and intestinal decompression. Because of the importance of peritonitis as a cause of death in penetrating wound of the abdomen the problem was of sufficient wartime importance to study the basis of chemotherapy in the light of the new advances in our understanding of the pathogenesis of morbid changes.

The authors produced necrosis of the appendix in dogs by ligature and studied the animals from the standpoint of various chemical and pathological tests. Peritonitis was produced in 91 control animals with a mortality of 41 percent. The majority of death occurred between 24 and 36 hours.

Nonprotein nitrogen level averaged 35 in the living group of animals and 46 in the dying group. Total protein concentrations showed a fall on the third postoperative day in the survivors a fall coincident with hemolysis. During the acute stage however there was no significant difference between these values in the surviving and dying animal. Chloride determinations were of no value in animals which received intravenous fluids as well as on those which did not. The results showed a real correlation between the chloride level and the outcome of the fatal cases. Survivors had a level above 100 mEq/l. and the fatal cases below 100 mEq/l.

INTERNATIONAL ABSTRACTS OF SURGERY

the two groups. Bacteriological examinations revealed that the pathogenesis occurred with almost equal frequency in the exudates of animals which survived and of those which succumbed. Further tests of the red blood count, white blood count, and hemoglobin showed no differences of significance in the dogs surviving and dying, although these values followed a typical course.

The only significant finding was the observation that blood taken during the crisis of peritonitis did not clot readily and when it did clot it was in the nature of a soft thrombus and clot retraction did not occur. Prothrombin time determinations were made at 24, 48, and 72 hour postoperative periods. It appeared that animals whose prothrombin times were consistently normal survived whereas animals whose prothrombin times were prolonged as much as 3 or 3 seconds at the 24 and 48 hour periods tended to die. An occasional animal in the latter category survived but remained in poor condition until the prothrombin time had returned to normal. Further more there appeared to be a relationship between prolongation of the prothrombin time and the severity of respiratory distress. As a result of this finding chest roentgenograms were taken at various periods. These indicated that there was a definite association between the onset of pulmonary disease and the development of prolongation in prothrombin time.

The prolongation in prothrombin time appears to be related to the failure of the clotting mechanism in the blood of animals dying of peritonitis and to the occurrence of hemorrhagic changes in the peritoneum, liver and lungs of many of these animals. Experiments with protamine indicate that it is unlikely that heparin is responsible for this finding. One obvious explanation is the development of severe injury to the liver parenchyma from anoxia or bacterial toxins. It is suggested that this mechanism may be a disturbance in the equilibrium of blood in circulating proteolytic and antiproteolytic factors. The study of the physical properties of blood in peritonitis indicate that the disease may be separated roughly into 4 stages and that these properties tend to shift simultaneously in the changes of the disease from one stage to another. It appears that changes in the prothrombin time not only reflect the various stages of the disease but also seem to be of prognostic value even before the onset of the disease crisis.

HAROLD LUTWAK, M.D.

Ricketts, W. E., and Palmer, W. L.: Complications of Chronic Nonspecific Ulcerative Colitis. *Gastroenterology* 1946; 7: 55

In a series of 306 cases of chronic nonspecific ulcerative colitis, complications were present in 64 (21.06 per cent). The complications were classified into five groups: (1) those involving the colon itself; (2) those involving adjacent structures; (3) those distant from the colon; (4) complications resulting from deficient nutrition; and (5) a miscellaneous group. The complications in the first group may be listed as follows: polyps in 21 cases (32.0 per cent); stric-

ture in 8 (3.9 per cent); obstruction in 6 (9.4 per cent) and carcinoma in 3 (4.4 per cent). Hemorrhage occurred quite frequently but there was no fatality from this cause. Ulcerated hemorrhoids were noted in 13 cases (6.8 per cent).

In the second group internal or external fistulae were found in 9 cases (4.4 per cent). Perforation with peritonitis was observed in 7 (3.4 per cent).

Complications distant from the colon were as follows: lesion of skin and mucosal surface in 23 cases (10.64 per cent), arthritis in 12 (5.83 per cent), venous thrombosis in 4 (1.94 per cent), hepatitis in 1 case (0.48 per cent) and septic infection in 17 cases (13.10 per cent).

Listed among the complications derived from deficient nutrition were malnutrition and atrophic colitis although the incidence and severity of the condition could not be determined. In a subgroup of 23 children there were 3 cases of infantilism, an incidence of 13.1 per cent. Peripheral neuritis was observed in 3 cases (1.45 per cent).

A miscellaneous group of complications included several conditions, viz., pleuritis in 5 cases (0.97 per cent) and endocarditis in 3 cases (0.94 per cent).

CHARLES BLUM, M.D.

Silani, C.: Suppurative Perisigmoiditis (Subperisigmoiditis suppurata). *Arch. Ital. Chir.* 94, 67: 110

Four cases of suppurative perisigmoiditis are reported by the author. 3 of the patients were adult males and 1 was a 9 year old girl. In 5 cases abscesses formed in the anteroinferior portion of the left iliac fossa and in 1 case the abscess was located in the retroiliac region. In 3 cases an incision and drainage of the abscess were done according to Roux's method while in the fourth case the pus drained spontaneously through the intestinal tract. All patients recovered. The condition may be acute or chronic. The acute type may assume a plastic or suppurative form and the latter may or may not cause a perforation. Two types of chronic perisigmoiditis may be distinguished: stenosing, plastic, and pseudotumoral. The condition may follow a trauma or may be the sequel of diverticula.

Pain fever and symptoms of peritoneal irritation are usually present. Differential diagnosis must be made from suppuration originating in the female genital organs, tuberculous peritonitis, appendicitis, abscess.

Röntgenological examination is essential for the diagnosis. Perisigmoiditis creates an image of intestinal stenosis with a smooth outline generally sometimes the image simulates that of a tumor.

The prognosis is usually favorable. External or internal fistulas frequently form and establish communication with the intestines, urinary bladder or vagina.

The treatment is surgical. A simple incision and drainage is sufficient unless perforation of a diverticulum is present when resection of a portion of the sigmoid may be required. JOSEPH E. NUGENT, M.D.

Torre, J., and Campos, E.: Surgical Treatment of Cancer of the Rectum and Sigmoid (Tratamiento quirúrgico del cáncer del recto y sigmoides) *Arch. cubanas cancerol.* 1946 5 32

The authors advocate a 1 stage abdominoperineal operation for cancer of the rectosigmoid region. They prefer an artificial anus in the iliac region to perineal colostomy. Urographic studies should be made in every case before the operation is performed because they may reveal a double ureter or another anomaly of the urinary tract.

In obstructive cases Devine colostomy is recommended.

The authors stress the importance of proper pre-operative treatment.

One operative team is sufficient. The perineal resection requires little time if the abdominal dissection has been done in the proper manner.

The operation is usually performed by the authors under spinal pantocain anesthesia and a blood transfusion is given during the procedure.

The resection should include the sigmoid rectum anus with its sphincter levator ani ischioanal fat mesosigmoid and pelvic peritoneum. The preoperative introduction of ureteral catheters is highly recommended because it contributes to the avoidance of lesions of the ureters.

It is important to suture the free border of the mesosigmoid to the abdominal wall to avoid the possibility of a hernia in the region of the colostomy.

Sim's position is recommended by the authors for the perineal resection. JOSEPH K. NARAY, M.D.

Yódice, A. R.: Surgical Treatment of Cancer of the Rectum (Tratamiento quirúrgico del cáncer del recto) *Arch. Soc. cir. hosp., Santiago* 1946 16 135

This article is an excellent résumé of the surgical management of rectal cancer. It presents the history of the operative treatment and the various techniques involved and relates the historical development of the three approaches—the perineal, abdominoperineal, and abdominal—employed in surgery for carcinoma of the lower bowel. Palliative treatment is reviewed under the title of colostomy which appears to have been used exclusively in the beginning and is retained to the present day as a preparatory step to any definitive surgery for bowel cancer.

The historical summary may be appreciated from the following outline:

1. Palliative treatment—colostomy cecostomy, Piloni 1776 lumbar colostomy Amussat 1839 and abdominal colostomy Allingham 1875

2. Curative treatment—resection via perineum, Koenig 1882 with previous abdominal colostomy. Resection amputation of rectum and adjacent tissue Lisfranc, 1856 sacral resection opening through peritoneum and sacral anus Bardhuber 1880, and Kraske, 1885 perineal resection removing stump of sigmoid after abdominal colostomy Lockhart Mummery 1908 Resection and anastomosis end to-end anastomosis Kocher 1875

via vagina Desquins 1890, and Murphy Tuttle 1900 via anterior perineal route Cunco, 1908 and by means of a glass tube, Lockhart Mummery 1908. Also anastomosis at different times Mikulicz Kuttner 1910 Resection from below through the anus preserving the sphincter Dieffenbach 1845 and via the terminal rectum pull-through or invagination Hochenegg 1888.

Curative treatment—resection exclusively through abdomen. Resection and anastomosis in different stages exteriorization and double-barreled colostomy Block, 1892 and Mikulicz, 1902 previous rectal mobilization Schoeffler 1903 and single-stage resection with double barreled colostomy Paul 1895 Resection and anastomosis per primam open method Reybard, 1833 and Dixon with colostomy preceding closed, or aseptic method Soulingoux 1896 and Wangenstein without previous colostomy. Resection and definitive abdominal colostomy closure of distal stump Hartmann 1923.

Curative treatment—resection via abdominoperineal route. With definitive abdominal colostomy Single stage—Miles 1908—extensive amputation of the rectum and mesosigmoid and Gay Turner 1934—preceded by perineal resection. Two-stage—Cooley 1915—(1) definitive abdominal colostomy and invagination of inferior barrel for rectal traction and (2) perineal resection D Jones 1915—(1) mobilization of sigmoid and pelvic peritonealization with abdominal sigmoidostomy superficial and (2) perineal amputation Turner and Rankin 1931—(1) definitive abdominal colostomy with closure of distal barrel and (2) perineal abdominal extirpation Lehey, 1930—(1) definitive abdominal colostomy with division and separation of the barrels and (2) extirpation, abdominoperineal.

Also resection and low end-canal—Maunassell 1892—mobilization abdominal after Dieffenbach, and low perineal, after Hochenegg and resection and end-to-end anastomosis—Volkman and Kocher—abdominal mobilization and perineal anastomosis.

Significant factors which must be considered in any surgery for carcinoma of the large bowel are the patient's age, length of illness psychological background, probable surgical reaction, location of the tumor and social standing of the patient.

The author recapitulates the general knowledge regarding the surgical anatomy associated with cancer of the lower bowel presenting numerous drawings. He believes that the importance of the critical point of Sudeck is exaggerated. He thinks that the danger point is farther to the left and designates it as the dangerous sigmoid point.

Operability depends upon the age of the lesion and the general condition of the patient at the time of first consultation and according to the author's experience as many as 85 per cent of the patients are operable.

The mortality depends upon the technique employed. In abdominoperineal resection it is between 10 and 12 per cent but since the introduction of chemotherapy this figure has been reduced to 7 per

INTERNATIONAL ABSTRACTS OF SURGERY

cent inasmuch as peritonitis is the principal cause of death.

Operation for cancer of the lower bowel requires upon the fundamentals of surgery during the operation and intelligent postoperative therapy.

Reoperative care must include the correction of constipation and disinfection of the rectum and sigmoid as far as possible. The patient should be put in a non blood transfusion and a selected dietary regimen. Twenty four hours preceding surgery a continuous spinal anesthesia should be inserted.

Clude the judicious use of the various peroperative methods employed in cancer of the lower bowel.

D'Errio, C.: *Cavernoma of the Liver: 2 Cases Treated by Hepatic Resection* (I. cavernoma del fegato 2 casi operati di resezione epatica). *Rivista* 1916 60 168

Two cases of cavernoma of the liver are reported both occurred in women. In the first case there was occasional attacks suggesting an acute abdomen condition a sallow color of the skin, bile in the urine high blood pressure (185/85 mm. Hg.) and indistinct yellow heart beat both over the upper and over the base of the aorta.

Laparotomy disclosed in addition to a somewhat enlarged gall bladder an orange sized, sessile, rather sharply demarcated tumor which was nodular and of a somewhat darker color than the liver tissue itself. It was situated on the under surface of the right hepatic lobe. The surface of the tumor was placed around the mass and it was excised, the resultant mass of the gall bladder being covered by an epiploic flap and by the caecum.

The patient died of acute cardiac insufficiency in the fourth postoperative day and autopsy disclosed in addition to the usual findings in heart failure and postoperative paralytic ileus the enlargement of the gall bladder already noted and also a moderate degree of intrabepatic cholangiectasia suggesting chronic cholelithiasis.

The second patient was apparently in robust health. Her only trouble was a tumor mass in the abdomen which grew in a few months from the size of an orange to that of an adult head. Physical and laboratory methods of examination showed the tumor to have pushed the lesser curvature of the stomach to the left and downward, and the spleen upward, to level with the level of the colon. The mass was freely movable with respiration and of a rather firm consistency with an irregular surface.

At laparotomy the dark red neoplasm was found to be attached to the under surface of the left lobe of the liver. Interlocking sutures were used to isolate the area of the tumor attachment and histological examination of the extirpated mass disclosed an angioma cavernosum. In removing this tumor a slight injury to its surface was incurred which resulted in bleeding that could be controlled only by extirpation of the neoplasm itself.

The author wishes to emphasize that this accident shows the danger to the patient of even insignificant abdominal trauma and the importance of early surgical treatment of the condition.

D'Errio, G.: *Hepatic Cavernoma from the Stomach Standpoint*. Critical Review of the Literature. 71 Operative Cases (I. cavernoma del fegato 71 casi operati). *Rivista critica della letteratura, Giornale chir.* 1915, 2 107

None of the statistical compilations from the medical literature of hepatic cavernoma seem to have been complete. A careful study of the literature up to the end of 1910 has disclosed 69 cases of hepatic

LIVER, GALL BLADDER, PANCREAS AND SPLEEN

Villan, J., Falcó A. and Duarte M.: *Nonparasitic Cysts of the Liver* (I. cisti non parasitiche del fegato). *Rivista* 1916 60 168

Nonparasitic cyst of the liver is a very rare entity to today about 200 cases have been collected. It may be unilocular or multilocular, solitary or multiple and are often accompanied by liver metastases. They vary in size from that of a pinhead to that of an adult head. In most cases they cause few symptoms unless they become large enough to cause pressure on the neighboring organs. If they are in the pedicle of the liver they may exert pressure on it and cause ascites or cirrhosis. The color of the cyst content may be yellow green red, or opalescent. The fact that these cysts frequently occur in association with cysts of the spleen or pancreas or that they sometimes occur with meningococci or polydactylism suggest a congenital origin. Familial occurrence is rare but Bunting has reported a case in 3 brothers associated with polycystic kidneys. The patients are generally in good general health as the tumors are benign but late in the disease there is a depression of the general health with emaciation profound malnutrition and anemia.

The authors describe 5 cases of their own 3 in males and 2 in females. The diagnosis of these cysts is generally made only at operation, as it was in the authors' cases. In the first case the preoperative diagnosis was stenosis of the pylorus in the second, hydatid cyst of the liver. In the third, the beginning of the menopause possibly associated with appendicitis or prolapsed kidney. In the fourth tumor of the floating kidney cholecystitis or stones. In the fifth operation was performed in 2 cases of solitary cyst and extirpation of the cyst in 1 case. Recovery was uneventful in all of the cases.

AUDREY G. MORGAN, M.D.

cavernoma which have undergone operation. To this number the author adds the 2 cases of his own which were reported in *Riforma Medica* (1946 60 168).

On examining the entire material of 71 cases it is seen that in 81 per cent a tumefaction could be palpated in the abdomen and in a few instances a connection with the liver was indicated but in the majority no connection seemed possible. Localization showed a preference for the left lobe while in most other conditions the right lobe is involved. X-ray examination—which was done in only 6 of these patients—has proved of no value in locating the disease. A "murmur" over the tumor and changes in size have been given as the basis for diagnosis in only 2 cases; however, one author noted only the absence of these characteristics of cavernoma. The symptoms of abdominal pains and digestive disturbances and even the rupture of the cavernoma have never led to the correct diagnosis; the usual condition suspected is an acute abdominal condition with subsequent operative or autopsy clarification of the condition. Although the female sex predominates (89.2 per cent) among the 56 patients of whom the sex was given and although these tumors have come to operation predominantly in the years of sexual activity, pregnancy has not proved to be a clear cut factor in their etiology or development.

The prognosis is less favorable than for cases of benign tumors in general because of the complications (of which the gravest is rupture of the tumor itself—spontaneously in 7 cases and during operation in 6) and because the location of the tumor renders excision difficult or impossible. In 1 case (Pazzi) rupture occurred following operation which made a total of 14 cases of rupture among which only 3 patients were saved. In 1 of the author's patients the tumor was injured at operation and the resulting hemorrhage could be controlled only by excision of the mass. Even this discussion of the prognosis does not give a true picture of the gravity of the condition since only the cases of patients operated upon are here recorded.

In 1 of the 7 cases of spontaneous rupture excision was done and in 6 direct hemostasis was attempted; there was only 1 recovery. In 5 of the 6 cases in which rupture occurred during the operation direct hemostasis was attempted with death of the patient in every instance and in the remaining case (the author's second) the patient was saved by hepatic resection.

Other methods of treatment than those cited have been: roentgen therapy which resulted in a marked diminution of the tumor mass in 3 instances; injection of a sclerosing liquid (varicocillin) in 1 case and tamponade of the nonexcisable tumor with gauze impregnated with vivocoll (coagulating animal plasma). These offer encouraging prospects for the future but the author is of the opinion that for the present hepatic resection remains the treatment of choice in the majority of cases of hepatic carcinoma.

JOHN W. BARNES, M.D.

Mirizzi P. L., Suárez G. V., Saravia E. G., San Martín A. F. and Others: Accidental Section of the Hepatic Ducts; Ligation of the Right Duct and Anastomosis of the Left to the Common Duct over a Vitallium Tube (Sección accidental de las ramas del hepático. Hecadura de la derecha y anastomosis de la izquierda al hepático común sobre tubos de vitallium). *Rev. Med. Argent.* 31: 1946 30 11 204.

A 31 year old woman had been suffering for 4 months from typical attack of gall stone colic. The gall bladder could not be visualized roentgenologically. At operation a Mayo incision was made under spinal anesthesia with percaine (7½ mgm.) and an enormously thickened adherent gall bladder containing numerous stones—one of which was wedged into the bladder neck—was removed in the retrograde direction. What appeared to be a shortened cystic duct was doubly ligated and sectioned. It was then noted that the hepatic duct had been ligated and sectioned at the level of the confluence of the two main and Basterreca and Medrano were called in on the case to reconstruct the bile passages. An attempt was made with a Y tube of vitallium; however, an assistant accidentally tore the right hepatic duct across which rendered its repair impossible. The torn duct was therefore ligated and the left hepatic duct was anastomosed to the common duct by a single vitallium tube bent at an angle of 175 degrees.

In the postoperative course there was an immediate elevation of the level of bilirubin which reached a height of 25 mgm. per 1000 c.c. of blood on the second day and then dropped to 16 mgm. from on the seventh to the twenty-first day to 12 mgm. on the thirty-eighth day and finally to 0 on the fifty-eighth day. Except for this sign of biliary obstruction the postoperative course of the patient was perfectly normal. Considerable bilirrhagia was noted but the authors believe that this leakage came from the anastomosis rather than from the ligated duct.

The authors conclude that the case confirms the experimental hypothesis of the innocuity of ligation of one of the hepatic ducts. However, they do not think that the results obtained justify the deliberate and intentional interruption of any part of the bile passages.

In the discussion SAN MARTÍN refuses to admit that the normal right hepatic duct was ligated and prefers to believe that the vessel ligated was a branch of a double duct or actually an accessory right hepatic bile duct which he asserts has been reported by De-comps in 10 per cent of his cases.

However, SUÁREZ believes that although the roentgenogram does appear to show that the vitallium tube might be projecting into a right hepatic duct in stead of left one, although the cholangiographic examination with air contrast cannot be repeated because of the fact that the biliary system has been completely closed, a careful study of the final postoperative intervention makes it possible to admit that the theory of Basterreca is correct. This is of great

upon the fact that this surgeon is a master of his craft and has worked for 18 years with another great master, Bengoela. He believes that his affirmation can be accepted that he actually had under his hands the hepatic hilus which was totally separated from the common duct, that the possibility of apposing more of the hepatic ducts has been abundantly demonstrated experimentally that the compensatory hypertrophy of the remaining hepatic tissue is known to be extraordinary and that the patient's ability to live comfortably with total apposition of the external secretion of the pancreas should suggest the same possibility with reference to the hepatic gland. This discussion cites 20 instances of biliary ducts occurred. He cites an instance in which the external secretion of the right lobe of the liver has been suppressed as demonstrated by cholangiography and finally he demonstrates roentgenograms showing such anomalies of the biliary tract in which extirpation of the gall bladder could have resulted in other than injury to the right or possibly both hepatic ducts.

FAVIANSEN declares that the cholecystectomy from the fundus to the neck of the gall bladder is liable to such accidents as are here discussed. In doubtful cases a portion of the bladder should be left intact rather than risk such an event, and that a cholecystectomy should be instituted as soon as the diagnosis of gallstones is made.

CAZZO and PASMAN declare that neither type of extirpation of the gall bladder from the fundus to the neck or the retrograde type can be held superior to the other, and that the best method will be determined by the local conditions found at operation. Injury to the bile passages will occur with either method. Pajama points out that the neck to fundus type is relatively bloodless because of initial ligation of the cystic artery, while the fundus to neck type is bloody. However he has obtained good results from the injection of adrenalin into the dissection. This method he attributes to suggestion made to him by Villegas.

JOHN W. BARNES, M.D.

Royer, M., Solari, A. V., and García, M. L.: Non surgical Cholangiography in Vesicular Lithiasis (La colangiografía no quirúrgica en litiasis vesicular). *Arch. argent. ciruj.* 1941, 1: 30.

Royer, M., Solari, A. V., and García, M. L.: Non surgical cholangiography for the exploration of the intra hepatic and extrahepatic biliary passages in 1940 and presented their article in November 1941. In August 1941 Lee of Philadelphia presented a procedure which he uses to visualize the biliary tracts by injecting a radio-opaque substance into the gall bladder during peritoneoscopy but there are no published results up to the present. Royer has confirmed that the work was done simultaneously and independently

in Philadelphia and Buenos Aires. After studying the paper of Lee, Royer found that the idea was the same, however the authors are more advanced in Lee visualizes only the gall bladder and, at times, the cystic duct rather poorly. Lee agreed readily to use their technique. Royer et al. are the only ones who have used and published the method showing an integral vision of the whole biliary tree, the physiology of the biliary ducts and roentgenograms of cholangitis. Mirizzi and Urrutia have compared surgical and non-surgical cholangiography rather inadequately.

For the following reason, the authors' method is more efficient than other methods of operative or postoperative cholangiography: previous laparotomy is unnecessary and peritoneoscopy is actually less compared to surgery. A study of the biliary passages, approximating normal, may be made, as morphine or general anesthesia being necessary, there is no shock due to peritoneal trauma and therefore the normal physiology of the biliary tract can be observed. This method allows visualization of the gall bladder which is not possible with other methods of cholangiography and, last, a study of the cystic, hepatic and common bile ducts may be made in the same manner as in other cholangiographies.

The method cannot be used in all cases and presents the following difficulties. If a very high or very low point is necessary for injection of the gall bladder, the immediate selection of another site is impossible. If the injection must be postponed for another sitting, injection into a much diseased and damaged gall bladder is contraindicated because of the danger of subsequent bile peritonitis and if the gall bladder is sclerotic in general, it cannot be observed or if it can be examined, injection is impossible because of nonexistent vesicular light reflex. However, these conditions are of little importance as both are indications for operation. Adhesions around the gall bladder, as in the omentum or colon, prevent visualization and injection. In 23 cases the authors failed to inject the gall bladder.

Twenty seven cases were diagnosed by this method and the condition diagnosed was confirmed by operation. The method is utilized in cases of obstructed gall bladder that is, when cholecystography is negative and there is no bile on duodenal sounding. Cholecystolithiasis is most probably the cause of the obstruction if in spite of the negative findings there are subjective symptoms of hepatic colic. These symptoms may be simulated by other processes, such as acute and chronic cholecystitis, external compression of the cystic duct and dyskinesia of the biliary passages.

Non-surgical cholangiography makes an accurate diagnosis of these conditions, establishing the prognosis and indicating the method of treatment, whether medical or surgical. In all cases in which cholecystography and duodenal sounding do not clear the diagnosis, the author's method will enable

one to diagnose the obstructed gall bladder easily. Also, the presence or absence of stones can be determined on visualization of the biliary tract. When the cystic duct is free, it is important to investigate the organic function of the gall bladder. A peritoneoscopy presupposes the examination of the gall bladder walls (fundus) and the form of this organ before an attempt is made to determine the normal or abnormal anatomic condition and complement this examination by provoking the evacuation of the gall bladder to see its functional state. Before in cases of nonobstructed gall bladder with negative cholecystography and good vesicular evacuation after duodenal sounding, the diagnosis of cholelithiasis offered difficulties but it is precisely in these cases that the authors' method confirms and assures decisive results. The value of the method diminishes relatively in positive cholecystographies although a sure diagnosis of cholelithiasis can be established and better visualization of the biliary passages can be obtained, especially with regard to existing calculi in the biliary duct. It is important to utilize the various positions in the roentgen examinations in a doubtful diagnosis of cholelithiasis in the ventral view a dorsal view should be taken, or vice versa. Also the motility of the stones may be observed in the different positions. The standing position suggested by Akertund may be applied to cases in which the visualization of stones in the gall bladder is difficult in the supine or dorsal position.

Among the advantages of the authors' method is the easy and effective diagnosis of cholelithiasis as the stone shadows appear distinct and intense

The length and integrity of the cystic duct may be observed which fact is much appreciated by the surgeon as it indicates the technical difficulties he will encounter but which cannot be deduced from the roentgen pictures. If the common bile duct is visualized up to the sphincter of Oddi exploration of these ducts during operation will be unnecessary.

There are some dangers that should be emphasized. To date 88 cholangiographies have been registered with no mortality nor infection except in 3 patients who had been operated upon from 8 to 10 days after cholangiography. Omental adhesions were seen at the point of vesicular puncture but in the other patients the point could not be ascertained. Only in 1 case with bile leakage in which complications were feared the patient had intense pain in the evening and on examination the next morning the bile leakage from the incision made for peritoneoscopy was revealed. With a larger cannula peritoneal examination showed no irritation. During the operation peritonitis without bile was found the liver and gall bladder were normal and the point of puncture was hard to find. After cholecystostomy the patient recovered uneventfully.

Two cases of erroneous interpretation were registered in the 144th observation a diagnosis of stone was made but the patient was operated upon 9 days after cholangiography and no stone nor point of puncture was found in the gall bladder and in the 160th observation the roentgen picture seemed to show 3 stones at the neck of the bladder but nothing was encountered at the operation.

A. B. VICENTE MD

GYNECOLOGY

UTERUS

Pavoni, A.: The Innervation of the Uterus (*L'innervazione dell'utero*) *Riv Ital S* 1944 37 5

The author gives a detailed review of the clinical and experimental work that has been done on the innervation of the uterus. Some authors have shown in animal experiments that the pregnant uterus contracts more or less regularly even when it has been completely isolated from the central nervous system by section of the spinal cord. Clinically spinal anesthesia isolates the uterus from the central nervous system and leaves it to be regulated by the autonomous ganglionic system of the organ itself. Under these circumstances the body of the uterus shows an increase of tone and decrease of contractions. While this shows that the spine has an inhibiting or regulatory action on tone and a stimulating action on contractions, it does not show whether the regulatory fibers run in the sympathetic or parasympathetic system. Moreover the cervix, unlike the body of the uterus, does not show increased tone when cut off from its spinal connections but can be dilated easily. Thus, however, does not prove that there is a sympathetic control for one of these parts of the organ and a parasympathetic control for the other. The most that can be said is that the autonomous ganglionic regulatory system of the uterus controls the tone of the body while that of the cervix is regulated by stimuli from the uterus itself although it is impossible to say whether the motor and sensory impulses run through sympathetic or parasympathetic fibers.

The sympathetic fibers to the uterus come from the lumbar and sacral tracts. It is possible, however, that some of the branches of the thoracoabdominal sympathetic may reach the adnexa through the utero-ovarian plexus. The parasympathetic fibers run for the most part in the pelvic nerve while the vagus plays little part in the innervation of the uterus. It is probable that as for other abdominal organs, parasympathetic fibers of spinal origin reach the uterus through the posterior roots, and that their spinal center is in the intermediate zone of the posterior horn.

The adnexa apparently receive fibers from the phrenic nerve also. There are more or less free anastomoses between the fibers of the hypogastric plexus and those of the internal spermatic plexus. The many sympathetic and parasympathetic fibers in the uterine musculature divide into delicate fibrils and run in all directions being distributed to all parts of the organ. It is not certain whether as in other hollow organs, there are intramural nerve cells or ganglia which constitute a true autonomous nervous system, but it is probable that the fundamental plexus of Boeck and the terminal reticulum of Stoeck act as an autonomic system. In any case the many ganglia

scattered along the extrauterine course of the sympathetic fibers are of great value in this respect.

The greater part of the efferent sensory fibers follow the sympathetic, of which the spinal centers are in the first and second lumbar and second and fourth sacral segments. Visceral pain is transmitted through these. The afferent branches for the uterus have motor inhibitory and trophic fibers, but it has been impossible either from clinical or clinicophysiological data to determine whether they are localized in the sympathetic or parasympathetic nerves.

While the pregnant uterus when separated from its connection with the central nervous system is capable of expelling its contents, the extrinsic innervation certainly has a function of co-ordination and regulation.

Many important problems in regard to the innervation of the uterus still remain to be settled and until they are settled it will be impossible to establish definitely the mechanism of the various functions of the uterus during and in the absence of pregnancy.

ARNOLD G. MONAGHAN, M.D.

Gianaroli, L.: Necrosis of Fibromas and Polyps of the Uterus (*La necrosi dei fibromi e polipi uterini*) *Riv Ital S* 1944, 37: 377

Fibromas and polyps of the uterus frequently undergo necrosis because of pressure of the fibrous tissue on the muscle fibers and blood vessels, followed frequently by secondary infection. Necrosis occurs particularly frequently in solitary nodules of medium size. There are various types of necrosis, the aseptic and soft types being most frequent, followed in frequency by the red, calcareous, and cystic necroses, the septic, myxomatous, and hyaline forms are rarer. Red necrosis is characterized by hemoglobin imbibition caused by extravasations of blood and is followed by necrobiotic degeneration.

The author presents statistics from other authors and discusses 111 cases of his own which were seen in 10 years at the Obstetrical and Gynecological Clinic of Bologna. Among a total of 6,573 gynecological examinations there were 303 cases of fibromas or polyps in a good state of preservation and 111 which had undergone necrosis. The average age of the patients in his group was 43 years. The most frequent symptom for which the patients came to the clinic was abnormal hemorrhage. The patients also presented pain, rise of temperature, a feeling of rapid increase in the size of the tumor and amenorrhea.

This complication of fibroma is most frequent during pregnancy and as the patient approaches the menopause. In about half of the cases the heart is more or less seriously affected but the blood pressure remains normal. Azotemia shows somewhat higher values than normal. Serious kidney lesions are rare but slight bladder disturbances are not in-

frequent. The symptoms insofar as they differ from those of ordinary fibromas or polyps are doubtless caused by the absorption of toxic substances from the tumor.

Treatment consists of removal of the uterus. It is a mistake to rely on conservative measures in the hope of overcoming the symptoms. Among the author's cases there were 6 deaths a percentage of 5.4 as compared with 1.1 among cases of tumors which have not undergone necrosis.

Four of the deaths were due to circulatory collapse 1 was due to bronchopneumonia, and 1 to acute purulent peritonitis. In 60 cases the post-operative course was absolutely normal while in the others it was complicated by fever for varying periods of time or by circulatory collapse.

AUDREY G. MORAN, M.D.

Marshall, W. Holloway A. L., Irby L. E. and Peacock, C.: *Inspissated Blood and the Growth of Fibromatous Uterine Tumors. Preliminary Report. Am J Surg.*, 1946 72 57

The author after discussing some of the hypotheses concerning the cause of uterine fibroids proposes a theory of positive chemotropism to account for their origin. He had noted after repeated intradermal injections of blood serum into his thigh that a large fibromatous area developed. He suggests that in the presence of chronic uterine infection blood is forced into the uterine stroma by the contractions of the uterus during menstruation. The blood becomes inspissated and attracts fibroblasts to the traumatized areas when the fibroblasts begin to grow the foundation of a tumor is laid.

Concerning the experimental production of fibrous tumors in animals by estrogenic stimulation he suggests that the increased blood supply may produce minute hemorrhages which are followed by fibroplasia. The injection of blood serum into one uterine horn and saline solution into the other in a young dog failed to produce tumor formation.

J. ROBERT WILLSON, M.D.

ADNEXAL AND PERIUTERINE CONDITIONS

Zuckermann C.: *Torsion of the Fallopian Tube (Volvulus salpingiano). Rev Mex Cir* 1946 14 35

The author presents a case of torsion of the fallopian tube, the third one he has seen in 20 years. This condition is rare because of the fact that the mesentery of the tubes is broad and short. So far there are only about 300 cases of this condition on record. The patient was a 23 year old nullipara who came with the complaints of severe lower abdominal pain and frequent vomiting of 24 hours duration. The menstrual history was irregular with the last menses occurring 10 days before the onset of the present illness. She also complained of a white vaginal discharge. The pulse temperature, and blood pressure were all normal. All laboratory examinations revealed normal values. The pertinent findings were as follows: marked lower abdominal pain, ten-

derness over the suprapubic and both iliac regions, slight enlargement of the uterus and both tubes and marked tenderness of the right adnexa. Because of the severe pain an exploratory laparotomy was done the following operative findings were noted: hematosalpinx of the right tube with torsion of its mesentery imminent perforation of the wall of the tube ovarian cysts about the size of an orange on the right side hydrosalpinx of the left tube, and chronic appendicitis with numerous adhesions.

The right tube and ovary, and the left tube and the appendix were removed. The abdomen was closed without a drain. The patient made an uneventful recovery. Macroscopic findings showed that the left tube was filled with serofibrinous exudate the mass being located at the distal two-thirds of the tube. It had the appearance of a neoplasm. The right tube was markedly engorged with blood. The cyst contained sebaceous fluid and some hair.

The pathological diagnosis was dermoid cyst of the right ovary and hematosalpinx with torsion on the right side.

The mechanism underlying the pathology was believed to be a hydrosalpinx which later developed into a hematosalpinx because of torsion of the mesentery. Practically all the cases of torsion of the tube recorded revealed an abnormally long tube and as a consequence, a long mesosalpinx. There was in almost all of the cases an accompanying ovarian cyst.

The author also reports a case of torsion of a normal tube. This occurred in a woman who was hysterectomized several years previously. He then cites the literature concerning torsion of the fallopian tube. In conclusion he suggests that this condition be considered in cases of acute abdominal conditions, especially when all other conditions have been ruled out.

SALVADOR S. TRINIDAD, M.D.

Rojas D. A.: *Ovarian Dysgerminoma (Dysgerminoma del ovario). Bol Soc Obst Gin B Aires* 1946 25 33

Rojas reports 4 cases of ovarian dysgerminoma, 3 observed in women less than 30 years of age and 1 case in a woman 36 years old. The menstruation was normal in all except 1 who started menstruating at the age of 9. In the last patient there were 3 pregnancies the first ended at 7 months with the birth of a child who died 19 days later. The second pregnancy ended in a dystocic delivery at the end of 9 months. The other 3 patients were virgins. The size of the tumor was that of the head of a fetus or of an adult in 3 cases and in the fourth case it was so large that it filled practically all of the pelvis and abdomen. In 2 cases the tumor was rotated and pathological evidence of defective irrigation could be found.

All of these cases have had a very favorable benign course and 3 have been followed up for nearly 5 years. In 3 cases a subtotal hysterectomy with extirpation of the adnexa was done and in 1 case only extirpation of the diseased ovary was done.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Parviainen, A.: On the Possibility of Nephelometric Examination of Proteinuria in the Prophylaxis of Nephrogestosis (Sur la possibilité de l'examen néphélométrique de protéinurie dans la prophylaxie d la néphrogestose) *Acta obst. gyn. scand.* 1946, 6 161

The appearance of nephrogestosis is the most disturbing complication of pregnancy and delivery.

The subjective symptoms of this condition are often mild and do not disturb the patient. During the usual prenatal examination the ordinary signs of nephrogestosis—swelling, elevated blood pressure, and impaired urinary function—are found late. Albuminuria occurs before these signs. The author considers all cases of albuminuria during pregnancy as pathological and has employed the so-called nephelometric test as the most delicate test to prove the presence of this condition.

The purpose of his work, the author states, is first of all to ascertain, with the aid of the nephelometric test, whether a determination of a minute amount of albumin in the urine made once in the course of pregnancy has any significance in nephrogestosis as to the prognosis during delivery and then to determine in the same individual the variations in the amount of albumin in the urine during pregnancy and labor and try, if possible, by these tests to determine the influence of excitement and eventual fatigue on the amount of albumin and the prognosis.

The nephelometric method which the author has employed is one modified and tried by Brummer. It is to be published at a later date. It has, among other things, proved that small amounts of protein, up to 1 mgm. per cent, can be derived from many substances, but those larger than 1 mgm. per cent come manifestly from albumin. The method is very simple.

A total of 310 specimens of sterile urine were examined by the author. All the specimens were taken from women from 3 to 10 months pregnant, the majority of the specimens being taken during the last part of pregnancy.

All the women tested had frequented the prenatal clinic from March to May 1945. Simultaneously with the nephelometric tests of the urine specimens the sulfasalicylic acid test and the test of Heller were done. The sulfasalicylic acid test was positive in only 5 cases (1.6%) and opalescent in only 3 of the cases. Heller's test was positive in only 3 cases (0.6%).

Following the nephelometric method, the presence of albumin (≥ 1 mgm.%) was proved in 103 (33.2%) of the total of 310 cases. The amounts of albumin were for the most part relatively small (from 1.0 to 1.0 mgm. %). By this method smaller quantities of albumin in the urine can be detected than by either

the sulfasalicylic acid test (in which opalescence begins only at 12.7 mgm.%) or Heller's test.

In 530 of the 310 cases examined, the results were checked at the time of delivery.

In only 2.0 per cent of the cases which showed less than 2.0 mgm. per cent of albumin by the nephelometric test the patients showed signs of nephrogestosis and these revealed a mild form of this condition.

Of the patients who showed more than 2.0 mgm. per cent of albumin by the nephelometric test, 53 per cent developed a severer grade of nephrogestosis.

Thus, with a single nephelometric albumin determination made relatively early in pregnancy the danger of impending nephrogestosis can be ascertained with great exactitude. By observing these cases more closely prophylactic measures can be employed to prevent the development of severe nephrogestosis. BLACKWELL, MARKHAM, M.D.

Harjois, O.: Studies on the Peripheral Blood Picture during Pregnancy and the So-Called Anemias of Pregnancy (Beiträge zur Kenntnis des peripheren Blutbildes während der Schwangerschaft und der sogenannten Graviditäts-Anemien) *Acta obst. gyn. scand.*, 1946, 16 7

The object of this study has been to clarify the nature of the blood picture in pregnancy and in anemia of pregnancy. An attempt was made to determine whether or not the anemia of pregnancy is associated with certain changes in the blood picture and whether the anemia of pregnancy is a true anemia or a manifestation of a hydremic state. Investigations were made with respect to the following factors:

1. Hemoglobin content of the blood,
2. Erythrocyte count,
3. Color index,
4. Reticulocyte count
5. Leucocyte and differential count,
6. Erythrocyte diameter and its range
7. Total and average volume of erythrocyte per cubic millimeter,
8. Volume index and saturation index of erythrocytes,
9. Serum iron
10. Examinations of the urine for albumin and sugar,
11. Stool examinations for parasites,
12. Test meals for free and total hydrochloric acid.

As a control group 16 healthy nonpregnant women were chosen for study. A second group consisted of 88 healthy pregnant women. The patients exhibiting anemia during pregnancy were divided into two groups: (1) those with mild anemia (hemoglobin from 60 to 69 per cent, Sahli) 71 patients and (2) those with severe anemia (hemoglobin less than

60 per cent, Sahli), 51 patients. Some of these patients were studied during several months of their pregnancies.

A review of the literature on hemoglobin values and erythrocyte counts during pregnancy reveals marked differences of opinion among various authors, most of whom conclude that these values are lowered. Some maintain that they are increased while others report that they are unchanged or variable. Studies on 82 healthy pregnant women indicate that hemoglobin levels and erythrocyte values are approximately the same for all months of pregnancy and correspond with the values found in the normal control group. In normal gravidas compared with nonpregnant women, the color index shows a slight rise, especially in the later months of pregnancy. The number of cases is too small and the range too great however to draw any definite conclusions from the increase of the average color index value. Reticulocyte values are fairly constant and show an increase from the fourth month on up to 35 per cent. It can be concluded that pregnancy gives rise to a brisk regeneration of red cells.

These studies show that there is a leucocytosis from the beginning of pregnancy the increase being more marked toward term but remaining within physiological limits. From the second month on, and becoming pronounced at the fourth month there is a shift to the left of the neutrophilic leucocytes. No consistent decrease of eosinophils was observed, although in a few cases they disappeared and in others they decreased. The basophilic leucocyte, lymphocyte and monocyte counts correspond to normal values. The mean diameter of the erythrocytes and the range of variation in individual cases showed no alteration when compared to the values obtained in healthy nonpregnant women. Pregnancy did not cause anisocytosis nor did it influence significantly the cell volume or saturation index. The values of serum iron appear to be increased during the entire period of pregnancy and especially toward term.

It was found almost without exception that in the group of pregnant women with mild anemia, having hemoglobin values between 60 and 69 per cent, the erythrocytes had decreased in proportion to the hemoglobin while the color index maintained a ratio comparable to that found in healthy gravidas. The average value for reticulocytes in all cases was increased about 13 per cent compared to values for healthy gravidas which indicated more active erythropoiesis. As in the group of healthy gravidas there was a leucocytosis, more marked in the last months of pregnancy. The neutrophilic leucocytes were increased from one month of pregnancy to the next, and the same shift to the left was observed as that in healthy gravidas. The range of the erythrocyte diameter was greater than in normal pregnancy and anisocytosis though slight was observed but the reduction in the amount of hemoglobin did not influence the mean value of the diameter of the red blood cells. The reduction in hemoglobin in this

group did not affect the cell volume nor saturation of the erythrocytes. From the sixth month on the serum iron showed a distinct decrease averaging 36 per cent compared with that of healthy gravidas who showed an increase in serum iron. This fall was not in direct proportion to the reduction in erythrocytes. A hypsideremia was noted as a result of the decreased hemoglobin. The secretion of gastric hydrochloric acid did not appear to be related to the serum iron level. It is concluded that the blood changes noted in the group of mild anemias of pregnancy represent a true anemic state which cannot be explained simply on a basis of hydremia or thinning of the blood.

In the group of severe anemias with hemoglobin values below 60 per cent (Sahli) it was found that the fall in hemoglobin was greater than that of the erythrocytes when comparison of mean values was made with respect to the healthy group of gravidas. The color index was decreased 20.8 per cent. A 50 per cent increase in reticulocytes on comparison with the nonpregnant group and an 11 per cent increase on comparison with the group having mild anemia was noted. The average values for leucocytes were increased over those obtained in healthy gravidas and were found to increase from month to month. There was no correlation between the decrease of hemoglobin and the increase in leucocytes. A shift to the left and an increase in neutrophilic leucocytes from month to month was found. The remaining white blood picture showed no departure from normal. The mean diameter of the erythrocytes was not affected by the diminished hemoglobin but anisocytosis was increased 18 per cent over that observed in healthy gravidas. Studies on the erythrocyte volume revealed cases in which the volume was normal and others in which it was decreased. Thus both normocytic and microcytic types of anemia were encountered. The diminished hemoglobin was associated with no significant change in saturation. The mean serum iron value was found to be decreased 61 per cent compared with the same value for healthy gravidas. The secretion of gastric hydrochloric acid did not appear to be a causative factor even in the most severe cases of anemia of pregnancy.

The author did not encounter malignant anemias of the pernicious or aplastic type in this series of cases.

JOHN L. LINDQUIST M.D.

LABOR AND ITS COMPLICATIONS

Johnson, H. W. The Clinical Diagnosis of Varying Degrees of Uterine Contraction Rings. *Am J Obst.*, 1946 53 74

It is assumed that the contraction rings generally reported are of the severe variety and occur with obstructed labors. Reasons are given for the firm conviction that a milder variety or subclinical and larger group occurs with otherwise unobstructed labors.

The maternal mortality operative incidence and fetal mortality as reported in a collective review of

the literature, are compared with similar figures obtained from treatment of a large series of subclinical or early contraction rings. The incidences of contraction rings in several institutions in Houston, Texas, are given to show the variance due to this complication of labor.

Early rupture of the membranes is believed to be a predisposing factor in the development of uterine rings. Temporary or functional rings are recognized. Cardinal signs and symptoms of ring dystocia are given and the development and diagnosis of these rings are depicted in diagrams. The usual methods of delivery in association with ring dystocia are described.

EDWARD L. CORNWELL, M.D.

Moracci, E.: Study of the Mechanism of Delivery in Brow Presentation. (Contributo allo studio del meccanismo del parto per la fronte) *Arch. ostet. g.* 1946, 51: 17.

The material for this study comprises 14 cases of frontal or brow presentation which were observed in the period between November 1, 1936 and October 31, 1943. Five of these terminated spontaneously and the author observed these personally. Five of the 14 patients were primiparas. The position of the fetal head during engagement in 5 instances was occiput left anterior and in 5 it was occiput right posterior, in 3 it was occiput right anterior and in the remaining case it was occiput left posterior. All deliveries except 1 were at term. The fetal weights exclusive of the premature infant were less than 3,000 gm. in 4 instances, between 3,000 and 3,500 gm. in 6 and between 3,500 and 3,750 gm. in 3. Thus, in 9 cases the weight was above 3,000 gm. which refutes the claims of some writers that the fetus in brow presentation is always premature.

In the 5 cases of spontaneous birth there were 3 fetal deaths. In the 9 of artificial delivery there were 6. The methods used consisted of a Thurn maneuver, a vertex presentation being substituted for the brow presentation; this resulted in a normal delivery with a live child. Version resulted in a dead fetus; forceps delivery in 2 cases resulted in a dead fetus; in each case the 2 cesarean sections resulted in the delivery of 2 living children and, finally, 3 craniotomies were done on fetuses which were already dead. The author thinks that these results should cause the profession to think seriously of extending the indications for cesarean operation.

In all 5 of the spontaneous deliveries the pelvis of the mother was normal and in all 3 the presentation never changed—the frontal bosses retained their relationship to the pelvic axis throughout the entire period of labor. In 2 cases the position was occiput left anterior; in the others it was occiput right posterior. In the latter 3 fetuses and in the 1 immature infant the face rotated anteriorly with the root of the nose under the pubic arch.

In the 3 normally developed infants the mouth could be felt to be widely opened during this process becoming fixed under the pubic arch. In the other rotation was not complete, the nose and superior

maxilla coming to rest under the ischiopubic cross in the vicinity of the subpubic angle, and the engagement was effectuated in a diameter intermediate between the right oblique and the anteroposterior (the parasagittal diameter of Matal). Even in this case the wide opening of the fetal mouth with the stemming of the border of the superior maxilla (hypomochlion of rotation) against the right ischiopubic ramus could be demonstrated.

The author admits that delivery may occur in brow presentations by other mechanisms and from other positions. For instance when the head penetrates in a transverse position or the face turns backward into the hollow of the sacrum and persists in this position; however he thinks that such mechanisms are the exception and not characteristic of the typical brow presentation. Madame La Chapelle thought that the greatest diameter of the fetal head (13.5 cm.) in the typical brow presentation passed down on an even keel, parallel to the plane of the superior strait (of which the greatest diameter is 13 cm.) by a marked process of molding of the head. Biancagelli thought that this diameter passed through the smaller diameter of the strait on a slant with the chin end lower than the back of the head. Polsson thought exactly the opposite, viz., that the occiput passed through the superior strait in a lower position than the chin. However, Alfieri concluded, on the basis of experiments in which he pushed the head of fetuses mounted on a universal joint at the end of a wooden stake down through the skeleton of pelvis, that in the typical brow presentation the fetal chin stems against the superior ramus of the os pubis and gives back as the mouth of the fetus opens widely. Thus the maxillo-sagittal diameter is substituted for the greatest, or mentosincipital, diameter and it is around this diameter (which is about 5 mm. shorter than the greatest diameter) that the fetal head rotates as a bascule to keep the frontal bosses always in the center of the pelvic axis.

It is this explanation of Alfieri that the author accepts, and in testing its validity he came upon his clinical findings of the open mouth of the fetus and conducted his cephalometric studies. In these studies the heads of 10 fetuses which had been born dead in the clinic were subjected to cephalometric measurements in a species of Broca cephalometer. The head was suspended in a position characteristic of the brow presentation, with the frontal bosses just touching the bottom of the box (which he designates as the plane of the frontal bosses). The other diameters were measured by means of movable points attached to the slide pieces which were graduated in millimeters. By this means it was found that with the mouth closed the average length of the mentosincipital, or greatest cephalic, diameter was 137.6 mm. and with the mouth opened it was 159.6 mm.

Also it was found that the new direction of the mentosincipital plane had changed from one practically parallel with that of the superior plane of the pelvis (plane of the frontal bosses) to one at an angle

of 10 degrees with the sincipital end entering the superior strait and passing down to leave the inferior strait before the chin entered the cavity of the small pelvis. Thus no flexion of the head (basale motion) appeared to be necessary until the sincipital end of the mentosincipital diameter had passed through the inferior strait and was resting on the perineum.

The author thinks that in this manner he has demonstrated the possibility of explaining the movement of the fetal head in brow presentation without the difficulties which have previously been considered insurmountable.

JOHN W. BRENNAN M.D.

MISCELLANEOUS

Lafont, A., and Curtillet A: Anatomoclinical Study of the Osteomalacic Pelvis (*Étude anatomo-clinique du bassin ostéomalacique*) *Gyn. Méd.,* Par., 1946, 45: 28

This report has been prepared by Lafont and refers to material accumulated during the period while he was working in collaboration with Curtillet in Algiers. The observations were conducted on the material in the museum of the University of Algiers and include clinical and roentgenological studies of several of the authors' own patients.

The stress of muscular pull is accorded only secondary importance in the development of the deformities characteristic of osteomalacic pelvis and the muscular factor is given but scant attention. The authors believe that the entire pathological picture can be explained on the basis of the interplay of forces when the weight of the upper part of the body passes downward through the spinal column to the sacrum and the "ground thrust" upward passes through the femur and hip joint. However, these forces produce different effects consonant with the different body postures, that is, on standing, sitting or lying, and this leads naturally to a 3 way division of the theme. However it is not to be understood that osteomalacic deformity seen in practice is a pure deformity that is that it is always the result of the forces in action only in the standing, sitting or lying postures. In the fully developed deformity an attentive study will enable the observer to distinguish the factors in the final result which originated while the patient was still able to walk about, from those which developed when the sufferer was compelled to abandon walking and sit or lie on his back or side.

While the patient is still ambulant the deformities which develop involve the superior and inferior rami of the pubis, the region of election of pelvic fractures and the sacrum, lumbar vertebrae, sacroiliac joint and posterior region of the iliac ala. The heavy, bony mass of the ilium lying back of and upward from, the glenoid cavity (the so-called sciatie spur of Latarjet and Gallios) encompasses the region of the *incrusa schiadicæ major* and resists deformity.

Anteriorly the pubic rami are crumpled inward and take with them the glenoid structures so that the socket of the hip joint comes to face anteriorly

Fig. 1 (Lafont and Curtillet) Deformity of the left side on lateral decubitus.

which diminishes the amount of abduction and external rotation of the femur. Of course in the last stages of the condition there are changes in the hip joint itself such as calcification of the labrum glenoidale and shrinking of the ligaments about the capsule which not only intensify the limitations of motion described but finally eventuate in inability to extend the hip joint itself. Posteriorly an exaggerated lordosis develops the sacrum is pushed downward tipped anteriorly and bent into a sharp hooklike deformity by the pull on its lower end by the powerful sacrotuberous ligament.

In the sitting posture the forces acting about the sacrum and adjoining structures continue, and in extreme cases even succeed in opening further the angle or dome formed by the massive resistant bony framework about the greater sciatic notch (spur of Latarjet and Gallios).

In the dorsal decubitus there are no important changes however if the patient lies upon her side the pressure of the body acts on the greater trochanter and region of the anterior superior spine of the ilium, exaggerating further the curve of the iliac crest and the inward deformity of the pubic ramus on that side so that the end result will be that depicted in Figure 1. Such extreme deformities are probably more common in Algerian women because of their oriental habit of sitting cross-legged on the floor.

Medical treatment, such as endocrine therapy, is not considered, the discussion being confined to the prevention or amelioration of the deformities consequent to osteomalacia of the pelvis in the female. Since the sacrum tends to lose its structural peculiarity of wedgelike or keystone-like integration into the sacroiliac joint and to hang loosely by the sacroiliac ligaments the author suggests doing an early sacroiliac arthrodesis by osseous implantation into the space between the angle formed by the posterior end of the iliac ala and the posterior aspect of the sacrum. This will perhaps prevent the development or accentuation of the downward and forward sinking of the sacral mass and the effect of the added calcium in the implant on the general calcium metabolism can be observed. The retraction at the hip joint might be relieved by sectioning of the ligament of Bertin. The author on 2 occasions has sectioned the pubic ramus, once from above downward in one

patient and from behind forward in the other in order to increase the space between the pubic bones and to make the vagina more permeable. In this way an appreciable correction of from 15 to 30 mm. was obtained.

JOHN W. BRENNAN M.D.

Vara, P.: Studies on Elderly Primiparas (Studien ueber alte Erstgebarende) *Acta obst. gyn. scand.* 1946, 26 S pp. 2.

Of 19,216 primiparas delivered at the Women's Clinic of the Helsinki University from 1927 to 1941 3,557 were 30 years of age or more. Of the latter 2,592 were from 30 to 34 years of age, 778 from 35 to 39 years, and 197 were 40 years or more. A comparison was made between full term deliveries in these patients and those in young primiparas under 30 years. A considerable increase in the number of older primiparas began in 1935 and has persisted. Breech position occurred in 3.38 per cent of the older primiparas, a slightly higher incidence than that observed in the younger group. Contracted pelvis and deflexion conditions showed no increase. Premature rupture was much more frequent in the older group, occurring in 23.16 per cent as compared with 0.86 per cent in the younger women. Early and late ruptures were less frequent in the older primiparas. The incidence of premature rupture was the same in cases with contracted and with normal pelvis, which indicated that contracted pelvis plays no part in the etiology of premature rupture. Of the various stages of labor the third was that showing the greatest difference in the older primiparas from that in young primiparas, although this too was only "apparent." Previous abortion definitely shortened the course of labor. The duration of labor in premature rupture was 6 hours less than in early rupture and 3 hours less than in late ruptures. Surgical delivery in full term pregnancies with normal pelvis was required in 22.43 per cent and was distributed as follows: forceps, 12.51 per cent, cesarean section 4.26 per cent, dilatation or uterine forceps 2.29 per cent, amniotic placenta manualis 0.95 per cent, craniotomy 0.26 per cent, internal version plus extraction 0.10 per cent. The incidence of surgical delivery increased with age, being 18.67 per cent in the age group from 30 to 34 years, 26.1 per cent in that from 35 to 39 years, and 42.6 per cent in that from 40 years and up. The incidence of surgical intervention for contracted pelvis was 41.9 per cent. The total incidence of surgical intervention in full term deliveries in elderly primiparas was 33.94 per cent, almost 50 per cent higher than that in young primiparas. Previous abortion seems to diminish the need for surgical intervention.

The incidence of nephrogestosis was no higher in the elderly than in the young primiparas, but cases of severe nephrogestosis, eclampsia, and eclampsia were more frequent in the older group. The total incidence of infection showed no increase in the older as compared to the younger patients.

As age advances the incidence of uterine myoma and extragenital disease is higher, including organic

cardiac disease. Primary weakness of labor pains was noted in 6.8 per cent of the elderly primiparas and secondary weakness in 18.21 per cent—over 50 per cent more than in young primiparas. Rupture of the soft parts occurred more frequently in the older group, but only ruptures of the first degree.

The bleeding tendency in the third stage of labor does not seem greater in elderly than in young primiparas, but atonic hemorrhages of less than 500 gm. occurred much more frequently in the older group, particularly in patients of 40 years or more. The incidence of placenta previa (0.28 per cent) was somewhat higher than in younger patients (0.09 per cent), but ablatio placentae ante tempus showed no significant increase as compared with that in the younger group.

Weak labor pains occurred considerably more frequently in the older patients. From the indications for forceps delivery it was evident that inertia, exhaustion, or both constituted about 40 per cent of the indications. Inertia and exhaustion constituted indications for cesarean section in 29.9 per cent, and in completed deliveries inertia occurred in 6.86 per cent and exhaustion in 18.21 per cent of cases, thus in twice as many of the older patients as in the younger group.

The maternal mortality in full term deliveries was 0.55 per cent (in spontaneous deliveries 0.12, and in surgical deliveries 4.1 per cent). In cesarean sections the maternal mortality was 4.9 per cent and in forceps deliveries 0.7 per cent. This mortality rate was considered as being "probably greater than in younger primiparas." The average weight of the infant, 3,535 gm., was definitely greater than that in the younger group. The general ratio of male to female infants in the entire material was 107.05 to 100.0, but in patients of 40 years or more the ratio was 136.6 to 100.

Asphyxia occurred in 7.36 per cent of the infants, being an indication for forceps delivery in 17.9 per cent and for cesarean section in 14.2 per cent of the cases. The infant mortality rate for full term deliveries was 3.07 per cent (corrected figures 2.70 per cent), and was definitely greater than that in young primiparas. In spontaneous deliveries the infant mortality rate was 2.23 per cent and in surgical deliveries, 3.6 per cent. In breech deliveries it was 8.1 per cent. In extraction cases, the infant mortality rate was 33.3 per cent in dilatation or uterine forceps cases, 18.5 per cent in forceps deliveries, 2.1 per cent, and in cesarean sections, 2.2 per cent. Premature rupture did not influence the infant mortality.

Premature deliveries occurred in 8.52 per cent of the older women, thus statistically they were only probably higher than in young primiparas. In premature rupture nephrogestosis occurred in 56.0 per cent (with eclampsia in 13.9 per cent, and eclampsia in 5.9 per cent). Ablatio placentae ante tempus occurred in 5.3 per cent of the premature deliveries. The incidence of surgical intervention was the same as in full term deliveries (23.1 per cent).

and the incidence of cesarean section was 6.9 per cent. The maternal mortality in premature deliveries was 2.3 per cent, and the infant mortality in the different weight groups was as follows: for infants weighing from 600 to 995 gm., 100 per cent; for those weighing from 1,000 to 1,495 gm., 67 per cent; for those weighing from 1,500 to 1,995 gm., 37 per cent; and for those weighing from 2,000 to 2,495 gm., 16 per cent.

Elderly primiparas may be classified into two groups, one group of constitutionally completely normal subjects and the other of infantile-hypoplastic and presenile parturients. The latter suffer more complications in delivery than the former. In infantile-hypoplastic women conception is retarded. If conception was retarded more than 2 years the incidence of surgical intervention was higher (28.9 per cent) and the duration of labor longer (27 hrs. 55 min.) than in subjects in which conception took place before the 2 year period (24 per cent and 15 hrs. 54 min. respectively).

The women requiring surgical intervention were shorter and stouter than those in whom spontaneous delivery was possible. The age of onset of the menses which was definitely retarded as compared with the younger group had no effect on the frequency of surgical intervention.

Since 1935 puncture of the membranes has been employed routinely to hasten delivery when the os uteri has opened to 4 cm. and the conditions are otherwise normal. Also cesarean section has been done promptly rather than expose the infant to the difficult forceps delivery. In the period from 1935 to 1941 rupture of the membranes was instituted twice as often as in the period from 1927 to 1934. The use of forceps delivery diminished from 19.16 per cent to 9.02 per cent, while cesarean section on the other hand increased from 2.19 per cent to 5.56 per cent. The maternal mortality rate fell from 0.88 per cent to 0.28 per cent and the infant mortality rate increased from 1.72 per cent to 3.39 per cent. However this last increase was noted only in spontaneous and breech deliveries and was attributable to employment of the majority of the regular nursing staff in Army work during the years from 1939 to 1941, which left the problem of deliveries in the hands of temporary workers.

Since the prognosis of both mother and child is less favorable in elderly primiparas these patients should receive most careful attention. A careful anamnesis and physical examination will reveal changes due to age as well as delayed conception. Elderly primiparas should always be hospitalized for delivery.

EDITH SCHANCK MOORE

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Fornl, P: Paroxysmal Hypertension Caused by Tumor of the Suprarenal Medulla (L'ipertensione parossistica da tumore medullo-surrenalico. *Arch. Ital. chir.* 1945 67 223.

The symptomatology of a suprarenal medullary tumor in a 32 year old man was complicated by tuberculosis of the kidney.

The author points out that a tumor with functioning chromaffine cells in the medullary zone of the suprarenal glands may be responsible for hyperadrenalinemia, which in turn may cause paroxysmal attacks of hypertension.

Removal of the tumor resulted in a complete cure.

JOSEPH K. NARAT, M.D.

San Martino, N: Statistical Report on 73 Patients with Unilateral Renal Tuberculosis Treated by Nephrectomy (Relazione clinico-statistica su 73 pazienti affetti da tubercolosi renale unilaterale nefrectomizzati) *Arch. Ital. urol.* 9 3, 80 809.

From a discussion of an extensive material the author hopes to be able to clarify the various guises under which unilateral renal tuberculosis may be found, and thus lead to a better understanding of the early diagnosis of this condition in order that surgical treatment may be given promptly.

Men were affected with kidney tuberculosis some what more frequently than women, perhaps because of their more frequent exposure to physical exhaustion and trauma. Those most frequently affected were in the fourth and fifth decades of life. There was a personal history of complicating tuberculous involvement of other organs in 44.1 per cent of the cases. These were subdivided as follows: tuberculosis of the lungs, 2.06 per cent, of the bones 5.4 per cent, of the genitalia 9.5 per cent, and of the pleura, 23.2 per cent. (Among his own cases the author found concomitant tuberculous involvement of the lungs in 1.03 per cent of the osseous system in 2.06 per cent, and of the genitalia in 12.3 per cent.) The symptomatology was predominately renal in only 13.6 per cent of the cases and predominately cystic in 67.1 per cent.

The author anticipates the most troublesome delays in diagnosis in the patients with symptoms of urinary colic suggesting calculus and those with hematuria suggesting tumor. The urine was clear and free of pathological elements in only 1.03 per cent of these patients. The tubercle bacillus was demonstrated in the urine in 53.4 per cent of the cases.

The author believes the most satisfactory method of demonstrating the bacillus of Koch to be centrifugation of a large amount of urine (1 liter) in the apparatus of Forsell and seeding of the sediment on Petrusian's medium with asparagine. The sur-

face of the plate is scraped after 7 or 8 days with a platinum loop and the material thus procured is transferred to a microscopic slide and stained by the method of Ziehl.

The affected kidney was removed under spinal anesthesia (2.5 c.c. of procaine hydrochloric acid in 4 per cent solution). The total mortality was 61 per cent: 3 patients (4.1 per cent) died on the day of operation, and 2 died some months afterward. All the others were cured of their symptoms, however, in 2 the symptoms reappeared some years later and tubercular involvement of the remaining kidney was found.

One instance of horseshoe kidney was encountered and in this the kidney was divided at the isthmus and the affected part was successfully removed.

JOSEPH W. BICHSEL, M.D.

Bouchard, R.: The Effect of Retrocortical Lithotomy on the Upper Urinary Tract (Le retentissement de la lithotomie rétrocorticale sur les voies urinaires supérieures) *J. urol. med., Par.*, 944-45, 51 551.

The routine use of urography in the study of the morphological changes produced by calculi has yielded interesting results. Pyelography reveals only the excretory passages, such as the ureter, renal pelvis and calices, but urography reveals more. In some urograms an opacity of the entire pyelocyst may be demonstrated, showing the effect of the calculus on the intraparenchymatous excretory passage and on the uriniferous tubule itself. In a urographic study of 38 cases of lithiasis, including 22 cases of calculi in the renal pelvis, 5 in the calices and 11 in the ureter the author observed an image which he believes to be of diagnostic significance. He feels, therefore, that urography should be the method of choice, especially since the dangers of introducing a probe into the ureter in cases of aseptic lithiasis may thus be avoided. This danger of infection has led to a more routine use of urography. With the aid of intravenous urography it is possible in a case of renal colic to demonstrate the cause as a calculus from the presence of dilated calices, even if the calculus has been expelled or is invisible in the roentgenogram. By this means a more favorable prognosis can be established in cases showing a marked dilatation above the calculus, a finding hitherto only too frequently taken as an indication for nephrectomy.

The significance of retrograde dilatation is wholly different from that of dilatation due to inhibition of the innervation. The former is a result of increased urinary pressure with resulting strain and eventual exhaustion of the muscle fibers. In the presence of irreversible lesions of this type, nephrectomy would be imperative. On the other hand, when it can be demonstrated that the dilatation is due merely to a hypotonia of the muscle fibers, the power of con-

traction may still be retained. Such a process permits of greater optimism. In spite of the recommendations for conservative treatment in urinary lithiasis nephrectomies are still done for dilatations considered irreversible according to classic interpretations.

The author believes that the theory of pathogenesis presented will permit extension of the indications for conservative operations. He emphasizes the utility of laying down any rigid rules in the presence of a physiology as complex as that of the urinary apparatus but hopes that his theory will help to limit the indications for nephrectomy in lithiasis.

The renal pelves do not show any changes roentgenographically in the presence of a calculus except for the distention due to the stone itself. In the calices, however, the calculus will produce either a multiplication or dilatation of the calices. In the latter instance, the calyx appears as a tube the papillary end of which terminates in an irregular or convex surface instead of in the ordinary cupule, and there is a rounded dilatation at the origin of the calyx resembling a grape seed. In cases of calculus in the ureter the urogram shows marked, regular sphenical dilatations at the level of the origin of the calices, but the pelvis and ureter appear normal. This is not in harmony with the classical theory of a retrograde dilatation. It seems more likely that a reflex hypotonicity is released by the ureteral segment traumatized by the presence of the calculus.

EDITH SCHAEFER MOORE

Garrey F. K., and Gombert, D.: Vaginal Ureterolithotomy. *J. Urol.*, Balt. 1946 56 49.

The authors present 13 instances of vaginal ureterolithotomy of which only 1 was unsuccessful. This swells the total of such cases recorded in the literature to 127. The single failure reported occurred when the stone slipped to a proximal position and the abdominal approach was necessary to recover the calculus.

To obviate this complication in the future the authors suggest fixing the stone in the ureteral position by wedging it with a ureteral catheter passed alongside of it.

The advantages and disadvantages of the procedure are tabulated. The salient advantages of the vaginal approach are less shock, rapid convalescence, and ease of operation, while the abdominal approach carries with it definite shock, difficulty of lower ureteral isolation, and postoperative hernia, along with a much more prolonged postoperative course associated with drainage. The abdominal approach, however, permits the exposure of a greater length of the ureter and thus a greater range of calculus excision and the advantage of increasing the incision for greater ureteral visualization. It is to be noted that these 3 advantages of the abdominal route constitute the only 3 disadvantages of the vaginal approach to a ureteral calculus in the terminal portion of the ureter.

Fig. 1 (Garvey and Gombert) showing cervix retracted incision through vaginal wall, exposure of ureter which has been incised, and calculus removed.

The authors report some slight but distinctly advantageous changes in the operative procedure of vaginal ureterolithotomy. A blunt curved hemostat is used to separate the underlying tissue after the lateral wall of the vagina is incised rather than finger tip dissection.

When the ureter is visualized following blunt instrument dissection an Allis is placed around the ureter above the stone, the ureter forceps is incised longitudinally over the stone and the latter is removed. The distal and proximal portions of the ureter are then dilated to prevent postoperative ureteral edema with obstruction. The ureter is closed with sutures in the adventitia. A small soft rubber drain is left in the wound but not against the ureter and the vaginal wound is closed. The drain is removed in 24 hours and the patient is permitted to be ambulant at this time.

The authors' method affords direct visualization of the ureter and thus the previous complications of uterine artery trauma with hemorrhage and vesical and peritoneal drainage should be avoided.

ROBERT LICH, JR., M.D.

Hill R. M.: Embryoma of the Kidney in the Adult. *Brit. J. Urol.* 1946 18 53.

The author reports the thirty-sixth case of a Wilms tumor in the adult. Of the 36 patients, only 4 have survived for an appreciable length of time. The patient whose case is now presented has sur-

vived 5 years. The course of the disease with a pathological description of the various reported cases, is given. It is noted that seemingly a Wilms' tumor is less malignant in adults than in children.

The treatment of nephrectomy plus irradiation is considered most satisfactory since the survival rate in this group was about twice that of cases in which surgery or irradiation was used independently. There are at least two instances of Wilms' tumor in the adult in which the patients have survived 4 and 10 years.

The case reported is that of a 35 year-old mother who experienced sudden abdominal pain associated with faintness. The patient complained also of some pain in her right side following exertion, and a year previously had had some irritative vesical symptoms for a few days. Examination revealed a large mass in the right renal area which moved with respirations. At operation using a transperitoneal approach the right kidney was found to be the site of the tumor and a smooth globular organ with dilated veins over the surface was demonstrated. Following nephrectomy the patient was given 3 500 roentgen units of deep x rays and during the past 5 years there has been no evidence of recurrence.

The renal tumor was ovoid in contour and measured 13 by 9 cm. with a lower pole replaced by an encapsulated blood cyst with yellowish bosses. Histologically the tumor revealed three principal cell types: (1) smooth muscles some of which were well differentiated and others of sarcomatous type, (2) lipomatous tissue well differentiated but some of which was primitive in type and (3) primitive blood sinuses.

The article is well illustrated and contains a full bibliography ROBERT LUCH, JR., M.D.

Kahle, P. J., and Schenken, J. R.: Aneurysm of the Renal Artery following Partial Nephrectomy. *J. Urol.*, Balt. 1946 56 1

Kahle and Schenken report the seventy ninth case of aneurysm of the renal artery following partial nephrectomy. The patient was a 33 year old white male who entered the hospital because of pain on the left side associated with hematuria. A renal calculus had been removed from the right side 4 months previously. The patient has a mild secondary anemia, a normal phenolsulfonphthalein reaction on each side, and a closely approximated circular shadows of calcareous density overlying the inferior pole of the left kidney and identified by pyelography as located within a dilated lower calyx. Partial left nephrectomy of the inferior pole was performed.

Because of distention 6 days after operation, an enema was ordered after which the patient complained of intense pain in the left lower quadrant and passed 600 c.c. of fresh blood and numerous clots. Intravenous infusions were administered, and 43 hours later a second hemorrhage occurred. The pelvis of the left kidney was irrigated with water and adrenalin solution. During the entire postoperative course the urinary output was consistently good.

The patient went to his home by ambulance, 10 miles away but again began to bleed and was returned to the hospital. In preparation for a left nephrectomy spinal analgesia was given, but the sharp drop in blood pressure contravened the operation. He was transfused several times and later discharged.

Fifty two days after operation the patient again began to bleed profusely. He was brought back to the hospital by ambulance and died a few minutes after admission to the hospital. At autopsy a mass, obviously an aneurysm, was found at the lower pole of the left kidney. The clot was composed of the usual laminations of fibrin, islands of agglutinated platelets, and masses of red blood cells and polymorphonuclear leucocytes. A small number of fibroblasts had invaded the clot in some areas. The wall of the aneurysm showed remnants of muscle fibers but for the most part was composed of chronically inflamed connective tissue or granulation tissue. A large number of macrophages filled with hemosiderin pigment were present in some areas around the wall. Immediately adjacent to the wall the renal tissue showed moderate interstitial fibrosis, a heavy infiltration with chronic inflammatory cells, and, in one area, a large mass of chronically inflamed granulation tissue which was continuous with the granulation tissue wall of the sinus tract. A section taken from the rounded protruding areas of cortex showed a diffuse infiltration of polymorphonuclear leucocytes in the interstitial tissues and in the tubules. Stains for elastic tissue showed fragments of dark fibers in the wall of the aneurysm. Bacterial stains revealed cocci and bacilli within the wall of the aneurysm and in the blood clot. Smears of the exudate in the sinus tract at the lower pole of the kidney showed gram positive cocci and gram negative bacilli. The mucosa of the bladder was intact in the sections examined, but an area just deep to the mucosa showed an infiltration of round cells. The histological diagnosis was mycotic intrarenal aneurysm with rupture into the renal pelvis, and chronic and acute pyelonephritis.

The authors comment that the sex distribution is slightly in favor of males. All the factors operative in aneurysm in other sites seem to be operative in this case, including trauma, infection, syphilis, congenital defects of the arterial wall, and periarthritis nodosa. The presence of a mass is an infrequent sign.

The diagnosis has been made on the basis of a ringlike shadow observed in x rays of the kidney, ureters and bladder the ring representing calcified deposits in the wall of the sac. Aortic arteriography has been employed for diagnosis. Treatment is prompt surgery, preferably nephrectomy. The surgeon must exercise extreme caution, and the possibility of aneurysm must be suspected in any case in which palpation of the renal fascia reveals pulsation and a bruit. A bluish discoloration of the flank indicates perirenal hemorrhage.

DAVID ROSENBLUM, M.D.

Pfeiffer G. E., and Gandin, M. M.: Massive Perirenal Lipoma with Report of a Case. *J. Urol.*, Balt., 1946 56 12

Pfeiffer and Gandin report a case of massive perirenal lipoma. This condition must be considered in the diagnosis of immense abdominal tumors. It is most commonly seen in females equally often on either side, and usually in patients between 40 and 60 years of age. About 35 per cent of retroperitoneal lipomas are of perirenal origin. There is no definite dividing line between simple hypertrophy of the fatty capsule of the kidney and perirenal lipoma. The tumor may arise from the renal capsule or perirenal tissue, it is retroperitoneal, of considerable volume may be fleshy and pseudofluctuant, hard and fibrous, or of any consistency between these two extremes, multilobular reddish or yellowish gray slightly vascular and surrounded by a capsule which permits easy enucleation. It may contain sarcomatous areas but unless malignant the growth is usually slow. It may displace the kidney or envelop it. Associated renal calculi may be present. Symptoms are due to compression and enlargement, such as vague gastrointestinal disturbances, mild backache, or increase in size of the abdomen. The tumor may reach enormous size. There may be weakness, fatigue, nervousness, genital and lower extremity edema, dyspnea, bloating, constipation, vomiting, diarrhea, melena, and eventually cachexia and death. Urinary symptoms are usually absent. Pressure may produce hydronephrosis, pyelitis and oliguria, ascites and dilatation of the superficial abdominal veins and varicocoele. Because of their size these tumors are frequently confused with large ovarian tumors, inoperable abdominal malignancy, ascites, pancreatic cyst, cirrhosis, and pregnancy.

The diagnosis should be considered in a large abdominal tumor in an adult from 40 to 60 years of age with mild gastrointestinal symptoms and backache with a history of slow growth, the tumor being relatively smooth, rounded, lobular, and soft. An x-ray film of the chest will show elevation of the diaphragm on the involved or both sides and there may be upward displacement of the heart. The gastrointestinal series will reveal displacement of the intestinal tract. The urine is usually negative but pyelographic studies will demonstrate a distorted ureter and displacement of the kidney. Transperitoneal nephrectomy is usually indicated. The prognosis is grave and recurrences are frequent.

The authors report the case of a 49-year-old white male who was admitted for treatment of an abdominal tumor. He was emaciated above the abdomen and had massive edema of the lower torso and lower extremities, and his abdomen protruded tremendously. The mass filled the entire right flank from the iliac crest to the left costal margin at the anterior axillary line. Retrograde pyelography showed the right renal pelvis to be displaced far into the left upper quadrant of the abdomen so that it lay farther to the left than the left renal pelvis. Upon opening the abdomen, the presence of an enormous lobular fatty

mass filling the abdomen was confirmed. It weighed 26½ pounds. The left kidney was in normal position. The primary incision was begun at the left of the ensiform made diagonally downward to the right, and terminated at the right flank. An additional left transverse incision was made. The renal pedicle was first clamped and tied and the tumor was delivered. Five yards of 3 inch gauze strip was used to fill the enormous dead space. The incision was closed with through and through interrupted alloy wire sutures and interrupted fine stainless steel for the fasciae. The pathological report stated that the gross specimen consists of tumor and kidney. The tumor is encapsulated and coarsely lobulated, approximately spherical in shape and 37.0 cm in diameter. Its weight is 26½ pounds. On cut surface it consists largely of fat and fibrous connective tissue in varying proportions. In some parts the fat predominates and in others the fibrous connective tissue predominates. The kidney is compressed and distorted. It is also atrophic. Its weight is 90 gm. The cortex is thin and averages 0.5 cm in thickness. The medullary substance is approximately 0.5 cm in thickness. The pelvis is compressed, and the kidney is probably nonfunctioning due to pressure. Study of several sections taken from different places in the tumor shows the tissue to consist of fat cells and fibrous tissue with the latter type predominating. There is no evidence of malignant change. Further search will be made by studying additional sections from other areas and if diagnosis is changed supplemental report will be made. Diagnosis: fibrolipoma, abdominal benign.

The patient was discharged on the seventy-second day after a stormy convalescence complicated by low serum protein for which human serum and amino acids were administered. Certain physiological alterations merit comment such as the edema, which was due to (1) pressure of the tumor upon the vena cava resulting in venous stasis distal to the point of compression and also (2) nutritional depletion caused by growth of the fibrolipoma at the expense of the remainder of the body and so contributing to the reduction of the total serum protein.

DAVID ROSENBLUM, M.D.

Moore T.: The Retrograde Movement of Ureteral Calculi. *Brit. J. Urol.*, 1946 18 60.

The author briefly refers to the literature and describes in detail Legeus's case in which the calculi were so extremely mobile that he placed the patient in the Trendelenburg position, shook him, clamped the upper ureter to prevent the stones from falling back into the ureter and then extracted the calculi from a renal calyx.

The case reported is that of a 22-year-old male with two stones which moved from the ureter to a renal calyx during the preliminary radiographic examinations. At operation the lower ureteral stone was extracted through a paramedian abdominal incision with the thought that the other stone could be milked down the hydroureter and removed through

the same ureteral incision. After the first stone had been removed the second was found not to be palpable. The ureter was then plugged and with a renal incision the renal stone was removed from a renal calyx. The sizes of these stones were $\frac{3}{4}$ inch and $\frac{1}{4}$ inch.

The need of x ray localization of ureteral calculi immediately before surgery is emphasized. Retrograde passage of ureteral calculi is dependent upon antiperistalsis or gravity. ROBERT LICH, JR., M.D.

Groffino, A.: The Histopathological and Pathogenic Study of Chronic Pericystitis, with Special regard to the Lesions of the Terminal End of the Ureter. (Contributo allo studio istopatologico e patogenetico delle pericistiti croniche con speciale riguardo alle lesioni del tratto terminale dell'uretere) *Arch. Ital. urol.*, 1945, 21: 139.

Anatomically, the urinary bladder is found to be surrounded by fibrous connective tissue which in part is covered with pelvic peritoneum. Smooth muscle is found at the terminal end of the ureter which aids the opening and closing of the mouth of this organ.

Chronic pericystitis may be subdivided into two types: (1) pericystitis of bladder origin and (2) that of extrabladder origin. In the latter type, inflammation of the adjacent organs or in some cases remote infection are the principal causes. This may spread either by direct extension or through the lymphatics. Pericystitis may be caused by attacks of appendicitis, typhlitis, sigmoiditis, proctitis, epididymitis, prostatitis, and colitis.

Pathologically two forms of pericystitis are present, the edematous and the sclerolipomatous. The edematous form is similar to pelvic cellulitis; it involves the terminal end of the ureter and results in obstruction. The sclerolipomatous form is characterized by fibrotic tissue interwoven with adipose lobules, and a hypergenesis of collagenous fibers with a decrease of cellular elements. This fibrotic process also involves the terminal end of the ureter and produces obstruction. The nerve supply to the bladder may also be affected by the edema or the fibrolipoma; this change and may give rise to disturbances of tone, bladder contraction and the painful crises that accompany it. Unless the anatomy and pathology of pericystitis is understood great diagnostic difficulties in establishing the true nature and site of the lesion are encountered. ARTHUR F. CROSSLAND, M.D.

BLADDER, URETHRA, AND PENIS

Niceley, E. P.: Gunshot Wounds of the Urinary Bladder in Wartime. *J. Urol.*, Balt., 1946, 58: 59.

Eleven cases of vesical injury are discussed: 1 of an extraperitoneal wound, 4 of intraperitoneal wounds and an associated injury of the abdominal viscera and, in addition, 4 of wounds of the bladder and rectum and 3 of vesical damage alone.

These cases present symptoms which vary with the size of the vesical opening, associated injury and

the length of time before the diagnosis is made. Intraperitoneal lesions present signs of shock in addition to urinary symptoms of vesical trauma, pain over the bladder region, urinary retention, and hematuria.

The diagnosis can be made readily when there is a large opening in the bladder by using the method of introducing fluid and noting the amount recovered. In smaller lesions cystography is often the most useful method, either with air or a halogen contrast media. Very small lesions can be most readily diagnosed by cystoscopy, but when an exploratory laparotomy is done cystoscopy may not be necessary.

An exploratory operation should be executed immediately after the diagnosis is made and the primary shock is controlled. The bladder should be opened, the openings repaired, and a cystostomy tube of large caliber left in place. The urethral catheter is removed. Urethral catheters may be introduced into the renal pelvis to keep the operative site free of urine. When intraperitoneal damage is associated with the peritoneal cavity is opened, the necessary repairs are executed, and the urine is removed distally is made without drainage. In combined vesical and rectal perforation both a cystostomy and a colostomy are to be done to divert both the urine and feces from the repaired area. The important factor in treatment is that the cystostomy tube be kept open and free of clots so that intravesical pressure does not be exerted at any time.

The prognosis in these patients is considered good provided that the diagnosis is made soon after injury and proper treatment is executed. In the opinion of the author complete recovery in a simple gunshot wound of the bladder may be anticipated in from 4 to 6 weeks after the time of injury. ROBERT LICH, JR., M.D.

Cortese, G.: Value of Urethrography in Male Genital Tuberculosis. (Valore dell'uretrografia nella tubercolosi genitale maschile) *Arch. Ital. urol.*, 1945, 67: 184.

Urethrographic studies in 27 cases of external genital tuberculosis in man enabled the author to establish the presence of involvement of the bladder or of the prostatic gland, while the clinical examination alone failed to reveal such involvement. In several instances the rectal examination disclosed prostatic and vesicular lesions while the roentgenograms furnished negative results. Conversely in other cases the rectal exploration failed to show any pathology while the urethrograms demonstrated complete destruction of the prostatic gland.

Urethrographic studies should be supplemented by laboratory tests such as cultures of the prostatic secretion, biologic tests, and search for tubercle bacilli in stained specimens.

Urethrographic studies of the deeply located genital following the evolution of the disease in its treatment tuberculosis and for the evaluation of its treatment. JOSEPH K. NARAY, M.D.

GENITAL ORGANS

Higbee, D. R.: Benign Prostatic Obstruction. *J. Urol., Balt.* 1946 56 83

The author compares the 3 types of prostatectomy in a series of consecutive cases done under spinal anesthesia.

In the group of 100 suprapubic prostatectomies 79 were two stage operations and 21 single stage procedures. The mortality in this group was 5 per cent and was limited to the two stage group. Of the 5 patients who died in this group 2 did not survive cystotomy, 2 deaths were due to a postprostatectomy septicemia and 1 death followed a large pulmonary embolus.

In the group of transurethral resections the mortality was 4 per cent. Three deaths in this group were due to heart failure and 1 was due to a septicemia following the removal of vesical calculi and prostatic resection.

The perineal group consisted of 100 patients with a mortality rate of 3 per cent. There were 3 deaths in this series: 1 due to heart failure, 1 to pulmonary emboli, and the last to carcinoma of the cecum.

The morbidity rate due to complications in the suprapubic group was 18 per cent as compared to 8 per cent in the transurethral group and 12 per cent in the perineal group. The average length of hospital stay was greatest in the suprapubic group and shortest in the transurethral group. However in the patients suffering complications the hospital stay was 45 days for the suprapubic group, 35 in the transurethral group and 28 days in the perineal group.

In reviewing the end results obtained after the 3 methods of prostatectomy there seems to be little difference. In short, then, the 3 methods may well be expected to give low morbidity and mortality rates and fulfill the purpose of surgery namely permanent symptomatic relief.

ROBERT LICH, JR. M.D.

D. Agata, A.: Biologic Reaction in 2 Cases of Tumor of the Testicle—Friedmann's Reaction (Reazione biologica su due casi di tumore del testicolo—Reazione di Friedmann). *Sperimentale* 1946 98 72

Two tumors of the left testicle are reported: one in a 31 year old laborer and the other in a 32 year old laborer. In both, the neoplasm appeared without history of trauma, and grew rather rapidly. There was no evidence in either patient of hereditary taint or of other disease, except that there was a positive Wassermann reaction in 1. In both patients the Friedmann reaction was positive before the testicle was removed. In one the reaction became negative a few days following the operation, but a month later it had again become positive coincident with the development of pain in the lumbar region and the appearance of what seemed to be metastasis in a lymph gland of the lumbo-aortic region. This suggests a prognostic value for the Friedmann reaction in this condition. In the other patient the reaction remained positive throughout.

The biologic reaction was also noted immediately upon removal of the tumor and the subcutaneous implantation of small pieces and upon the intraperitoneal injection of triturated suspensions of the tumor. In the first patient cited, the reaction proved negative for the implantation but positive for the intraperitoneal injection. In the second case the reaction was positive in both instances.

Both tumors were diagnosed histologically as seminomas. However the positive Friedmann reaction showed that there may also have been present some elements of a teratoma with the inclusion of chorio-epitheliomatous cells and in the second case cited the microscopic picture of some fields exhibited structures strongly suggestive of Langhans cells. The author therefore, leans toward the view that these tumors are unilateral developing teratomas of the testicle.

JOHN W. BRENNAN, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES, TENDONS, ETC.

Wertheimer, L. G.: Limitation of Movement of the Scapulohumeral Joint by a Muscle Anomaly (Limitação dos movimentos da articulação escapulohumeral por anomalia muscular) *Rev Hosp Clin.* 1946, 1: 191

It is very rare for the movement of the shoulder joint to be limited by the presence of an anomalous muscle. The author describes such a case in a young man of 20 years. The right anterior axillary fold was very abnormally developed, extending to the middle of the arm when the arm was abducted. In addition to this deformity the patient presented dorsal scoliosis and absence of the palate. His mind was normal. Examination of the right side showed a chondroepitrochlear muscle, apparently with two muscle bundles uniting in a tendon which passed to the epitrochlea. On the left side there was a similar but much smaller muscle. The chondroepitrochlear muscle on the right side was found to react to electrical stimulation of the brachial plexus. There were no qualitative or quantitative abnormalities in the reaction. The pectoralis major muscle was much smaller than normal. It also reacted to electrical stimulation but the contractions were rather weak.

Operation was performed on the right side for the purpose of freeing the movements of the shoulder

Fig. 3. (Wertheimer.) Turning back the skin flap and sectioning the aponeurosis, it is found that the chondroepitrochlear muscle presents a lateral bundle which at the upper end is divided into two bundles, 'a' and 'a' and a median bundle 'b' which is directed toward the thorax. The vascular bundle of the arm is seen between the biceps and the chondroepitrochlear muscles. The pectoralis major muscle is seen to be very small.

On sectioning the two muscle bundles felt on palpation a third bundle was found beneath them. The two superficial bundles were sutured to the lower surface of the tendon of the pectoralis major and the third shorter one was fixed to the middle of the other two. Immediately after the operation the arm could be lifted to maximum ante flexion. A thoracoplasty cast was applied in a position of hypercorrection. This operation not only restored normal movement of the arm but the action of the pectoralis major was strengthened by the attachment of the muscle bundles to it.

AUDREY G. MOORE, M.D.

Billing, L., and Ringertz, N.: Fibro-Osteoma, a Pathologicomorphological and Roentgenological Study. *Acta radiol.*, Stockh., 1946, 27: 179

This study undertakes to clear up some questions on the pathology of fibro-osteoma, and stresses its possibilities for roentgenological diagnosis. A survey of the literature is made, although the great variation in nomenclature makes evaluation of the one difficult.

Most of the benign tumorlike new formations of bone in the skull may be grouped as a pathological entity but the great variation in tissue maturation makes them differ widely in pathological appearance. The term fibro-osteoma is used to define lesions having a distinct anatomical connection with the skeleton and in which there is a ground substance of connective tissue containing clumps and spicules of bone tissue. The relative cellularity vascularity and maturity of the involved tissues vary so that the tumors range from the soft, predominantly fibrous, to the chondrified osteomas. No cartilage is found in these tumors, which fact distinguishes them from osteochondrogenous exostoses.

A series of 25 cases is presented in a tabular survey and the discussion stems from the findings in these. Photomicrographs illustrate the stages of maturity of tissue described in various individual lesions or even combined in the same tumor. Regressive changes often occur in the more mature type of tumors with osteoclasts in part or all of the lesion. When the bone-dissolving process is terminated the giant cells disappear and only a fibrous mass remains.

The anatomy is best demonstrated by roentgenograms of thin slices of tumor because photomicrographs are marred when other parts lie over the tumor. The lesions may be localized, solitary or multiple causing swelling of a part of a cranial bone or of the entire bone, and when several bones are involved the suture lines are obliterated. In some projections it is possible to show the thin cortical shell delimiting the mass.

The jaws are sites of predilection the frontal sinus and ethmoidal area also being common locations. In diffuse involvement the condition may be unilateral or include the entire face and anterior skull.

The most common types of importance for clinical and roentgenological diagnosis are divided into 4 classes and described in detail. All occur chiefly in youth with active growth about puberty and produce symptoms of a mechanical nature due to deformity of the bone. Retardation of growth is often spontaneous, and when tumor tissue is of a mature type there is rarely recurrence after simple removal. Malignant degeneration is not unusual but the tissue may be mistaken for osteogenic sarcoma and intensive irradiation may result in sarcomatous degeneration.

As to the pathogenesis fibro-osteoma is probably not a true neoplasm but a growing malformation similar to the embryonal development of membrane bone. One case in a rib is noted with roentgen and pathological findings identical with the cranial type of fibro-osteoma. The osteoid osteoma of Jaffe is recognized as being pathogenetically dissimilar.

FRANCES E. BRENNER, M.D.

Roth R., and Raider L.: Primary Malignant Bone Tumors. *Am. J. Roentg.* 1946 36 75

Of the 235 cases of primary malignant bone tumor seen in the Radiation Therapy Department at Bellevue Hospital in the past 20 years 114 were too advanced for any treatment. The 121 treated cases fell into the following groups (Classification of Registry of Bone Sarcomas American College of Surgery) (1) osteogenic sarcoma, 45 cases (2) chondrosarcoma 8 cases (3) endothelioma, 32 cases, (4) multiple myeloma, 18 cases and (5) giant cell sarcoma, 18 cases.

Fig. 2. (Roth and Raider) Original roentgenogram showing osteocartilaginous tumor the margins of which are still intact.

Fig. 1 (Roth and Raider) Osteogenic sarcoma. Left, Appearance at time of admission, showing destructive lesion of the upper third of left femur. Right, Following radiation therapy showing regeneration of bone.

Fig. 3. (Rosh and Raider) Chondrosarcoma, appearance at last admission

In spite of controversy on the value of irradiation therapy, the impression remains that the best hope of cure lies in the combination of intensive irradiation and surgery. The tumors are radiosensitive in the following order: endothelioma, multiple myeloma, giant cell sarcoma, osteogenic sarcoma, and chondrosarcoma. The procedure of working up each case is outlined together with the technique of irradiation.

Twenty two of the 45 cases of osteogenic sarcoma occurred in patients under the age of 20 years. In the following two decades there were 5 and 3 cases, respectively. There were 18 cases, more of the osteolytic type, among the patients more than 40 years of age. Most of the cases (32) had metastases and were therefore treated by irradiation only. In 14 cases excision also was done, with 6 survivals for 1 year and 4 for 5 years. Of the 3 patients who underwent amputation after irradiation 2 survived 3 years, and 1 5 years. Coley's serum appeared to make no appreciable difference in the results.

Chondrosarcoma, which may arise primarily or in a pre-existing chondroma or osteochondroma, was found in 8 patients. Three of these survived more than 5 years, and all of them died of pulmonary metastases. Again, intensive irradiation followed by excision or amputation when feasible, was the method of treatment.

Endothelial tumors known as Ewing's tumors metastasize early and rapidly to the lungs, lymph nodes, and the skeletal system. Of the 32 patients with this condition 20 were under 20 years of age, and only 1 was known to be a survivor after 5 years. Although the irradiation may be used diagnostically the pro-

Fig. 4. (Rosh and Raider) Giant cell sarcoma. Left, Shows destructive lesion expanding the bone with dissolution of the cortex medially. Right, Same case, 6 months later following irradiation therapy shows regeneration of bone.

nosis is poor since not over 10 per cent of the patients are permanently cured by the best of treatment.

Multiple myeloma is invariably fatal and the 'punched out' areas of osteoporosis are often the site of pathological fractures. Irradiation is palliative, often permitting fractures to heal and yielding symptomatic relief. Of the 18 patients with this condition only 7 survived 3 years.

Giant cell sarcoma is not particularly radiosensitive, but it yields the greatest percentage of cures to radiation therapy. Excision and radiation are the authors' preferred treatment, and there may be complete regeneration of the bone following such therapy. Of 18 patients 6 underwent excision and irradiation treatment and of these, 4 were alive and well 3 years later. Four patients received irradiation treatment only and of these, 3 were well after 3 years.

Early recognition of malignant bone tumors followed rapidly by intensive treatment offers a good chance of permanent cure. The radiation therapist is of increasing importance in making the diagnosis and then prescribing and giving the irradiation therapy.

SURGERY OF THE BONES, JOINTS MUSCLES, TENDONS, ETC.

Lattes, R., and Frantz, V. K.: Absorbable Gauze in Bone Surgery. *Ann Surg.*, 1946, 124, 28.

This is a report of a series of experiments in which oxidized cellulose (absorbable gauze) fibrin foam and absorbable gelatin sponges were placed in cortical cavities or between the fragments of fractured bones of dogs.

By using the three substances in adjacent ribs of the same animal individual variations in tissue reactions were eliminated as a source of error.

Osteogenesis was markedly retarded by the presence of absorbable gauze, but fibrin foam or absorbable gelatin permitted healing almost as rapidly as that seen in control defects.

This interference with bone healing by absorbable gauze whether it was placed in cortical defects, fracture lines, or in a bone from which a segment had been removed suggested to the authors that it may be a valuable material for use in arthroplasties. Preliminary trials in this work have been encouraging.

NEWTON C. MEAD, M.D.

-Snedecor S. T.: Bone Surgery of the Hand. *Am. J. Surg.*, 1946, 72, 303.

A series of 10 cases in which various types of bone surgery accomplished an improvement of function in severely deranged hands are presented with excellent illustrations. Bone surgery was not undertaken unless it would assuredly restore added usefulness to the hand, and was always considered in relation to the condition as a whole. Surgery of the bones cannot be performed on the hand through scar tissue. Good skin with subcutaneous tissue was a prerequisite for this work. Occasionally nerve grafting or

Fig 1. (Snedecor) Left, Useless remnant of index finger with loss of head of second metacarpal. Apparent non-union of the metacarpal but at operation it was found to be firmly united. Right, removal of second metacarpal and transplant of distal half of fifth metatarsal onto shaft of third metacarpal after restoration of joint space. (Courtesy of American Journal of Surgery.)

neurolysis was performed earlier or at the time that the bone work was done.

A few cases with loss of thumb function were treated successfully. In 1 case in which the first metacarpal was gone, surgery consisted in the transfer of a useless metacarpal (the phalanges had previously been amputated) over to the thenar side and into the greater multangular. In instances in which this metacarpal was not available a tibial graft was occasionally used. There were instances in which the opposing action of the thumb was lost. In 1 case there was destruction of the thenar muscle with dense scar contracture. This problem was solved by freeing the scar and bringing the thumb around in an opposition position. A small bone block was taken from the tibia to hold it. This was wedged down between the first and second metacarpals and held in place by a Kirschner wire. In another case in which opposition of the thumb was lost because of scar tissue contracture, the thumb and remaining fingers possessed fair flexion and extension power and after the scar was freed an osteotomy was performed at the base of the first metacarpal and the shaft was rotated. This permitted it to move into a position of opposition to the index finger when a subsequent tendon transplant was made to motivate it. In cases in which the first metacarpal base was dislocated up into the wrist reduction was difficult but the condition was corrected by fixation with Kirschner wires which were removed within 5 or 6 weeks.

In malunion of the metacarpal fractures particularly in the cases in which the metacarpal heads had dropped forward the whole intrinsic muscle mechanism of the fingers was thrown out of gear. Severe extension contractures of the

metacarpophalangeal joints developed and at operation it was often necessary to do a capsulectomy on the collateral ligaments of these joints in order to obtain 90 degrees of flexion. Fixation was accomplished by running Kirschner wires through the heads of several metacarpals to hold them up in place until healing occurred. Postoperatively the metacarpophalangeal joints were maintained in a position of 90 degrees flexion for 2 or 3 weeks in order to prevent the recurrence of these extension contractures. At the same time active use of the phalangeal joints was encouraged to prevent stiffness of the fingers.

The closer to the normal length the metacarpals could be restored, the better was the ultimate function of the hand. Preliminary skeletal traction was found useful in accomplishing this. A bone graft was inserted subsequently. The problem of solving the loss of a metacarpophalangeal joint of an important finger was accomplished in the case of a blind officer whose finger function was truly important. The index finger was already missing so that its metacarpal stump had to be removed to eliminate scar tissue and make a smooth cleft between the thumb and middle finger. The space formerly occupied by the head of the third metacarpal was filled with dense scar tissue which had to be meticulously dissected out. A soft tissue covering was then prepared. The distal half of this third metacarpal was then borrowed for the graft and was notched into the proximal end of the metacarpal and fixed with a Kirschner wire. This single contact graft grew perfectly and the joint moved well. The flexor tendon had remained intact. Later after union of the graft and motion in the joint had been well established, an extensor tendon graft was added and the finger functioned very well.

Cases were described in which the metacarpals were shifted to replace the loss of more important bones. In 1 case the distal end of the fourth metacarpal was missing and the finger was without nerve and tendon supply. This finger was sacrificed, and the fifth finger was moved over to take its place by the shifting of its metacarpal over to the base of the fourth.

Numerous arthroplasties of the metacarpophalangeal joints were successful. The base of the first phalanx in 1 case was trimmed up neatly and the sleeve mechanism around it was adjusted. In other cases the deformed heads of the metacarpals were replaced.

C. FRED GORDON, M.D.

Möllerud A.: A Case of Bilateral Habitual Luxation in the Posterior Part of the Shoulder Joint. *Acta chir scand* 1946, 94 181

The author describes a case of bilateral habitual luxation of the posterior part of the shoulder joint. A comparison is made with 2 other cases of posterior luxation of the shoulder reported respectively by Asplund and Sjövall.

The case was that of a domestic servant aged 18 who complained that she felt her shoulder slip as if the arm had gone out of joint when she performed

certain movements. There was no pain but she noted that the arm got tired, particularly during heavy work which involved constant luxation and reposition. She had noticed this for several years in the left shoulder and approximately 2 years in the right.

In the case described by Sjövall the patient was a powerfully built man aged 22 who by stretching the arm forward and upward during inward rotation could constantly produce backward luxation of the limb. Asplund's patient was a young man aged 18 in whom backward luxation of the shoulder joint could be produced by abducting the right arm to about 90 degrees, then stretching it forward during simultaneous inward rotation. This was true of both shoulders. In the former's case roentgenograms were negative, but in the latter's, they revealed flattening of the posterior part of the glenoid cavity while arthrography indicated an insufficiency of the capsular apparatus and an abnormally large posterior recess. These findings were verified at operation.

In Möllerud's case the mechanism of the subluxation was thought to be as follows: the more the arm approached the described position of upward and forward extension with simultaneous inward rotation, the more favorable were the conditions for posterior luxation. The outward rotators which brace and support the capsule posteriorly would be lax since the antagonists were in action and the tendon to the caput longum of the biceps, which acts as an intra articular supporting ligament, would make the least resistance to a backward movement of the caput humeri. On the other hand outward rotation would hinder luxation. The outward rotators would then presumably be somewhat supported and with them the posterior part of the capsule even if it were abnormally slack.

Concerning the etiology it was believed that the condition was one of capsular insufficiency of congenital origin with abnormal laxity of the shoulder joint capsules, which allowed the subluxation to occur without trauma or defect in the capsule. This viewpoint was supported by the fact that the occurrence was bilateral. In Möllerud's case the luxation could be brought about without inward rotation, in contrast to the cases described by Sjövall and Asplund. In their cases the inward rotation was required in order to produce luxation. Accordingly Sjövall concluded on the basis of x-ray examination and postmortem experimental findings that the mechanism of luxation was as follows: on elevation and inward rotation of the arm the tuberculum minus thrusts against the glenoid cavity so that the caput humeri is pushed out of the socket and at the same time glides backward. In order that this may occur the capsule of the joint must be abnormally lax, especially in the posterior part. Thus, in post mortem experiments it was necessary to cut entirely through the capsule before luxation could be produced. In Möllerud's case the condition caused only slight inconvenience and operative treatment was not carried out.

C. FRED GORDON, M.D.

Freiberg, J. A.: Experiences with the Brittain Ischiofemoral Arthrodesis. *J Bone Surg* 1946 28 501

The rather high incidence of failure of osseous fusion following the use of standard iliofemoral operations, especially in the tuberculous hip, has been due to the distraction effect of the adductor muscles on the superiorly and laterally placed graft and in some cases to the presence of diseased bone in the superior portion of the acetabulum.

Brittain has pointed out that the mechanical strength of the ischiofemoral strut graft placed inferior to the hip joint, is superior to that of the tying buttress graft of the iliofemoral type. The former graft heals under compression force, while the latter must heal under tension—the force in both instances is supplied by the adductor muscles of the hip and thigh.

The basic principles of the Brittain ischiofemoral operation are simple. An adequate, rigid tibial graft must be firmly implanted in healthy pelvic bone. The proximal end of the distal femoral segment must be displaced medially to the ischium so that new bone need not develop across the dead space bridged only by the graft. Uniform contact between the cut surfaces of the femur and the graft ensures moderate immediate fixation, early healing and maintenance of the original operative position. In patients with tuberculous lesions the osteotomy should be done at a level and at an angle which will allow the graft to be embedded in bone not involved in the infectious process. The angle of osteotomy should vary according to the specific relations of the damaged hip joint, from the transverse plane to an angle of 45 degrees.

The indications for the Brittain ischiofemoral arthrodesis are multiple. The contraindications occur in those instances in which the diseased bone cannot be short-circuited by means of the osteotomy and graft.

The author performed 7 Brittain ischiofemoral arthrodeses in a period of 7 months and waited 6 months to determine the results in these cases prior to continuing this procedure. End result studies are reported only for these 7 patients operated upon from 13 to 20 months previously.

Among 6 patients with tuberculous hip joints upon whom the Brittain ischiofemoral arthrodesis was performed, osseous fusion developed in 4 within from 7 to 9 months. In 1 case, with postoperative extraneous complications, fusion is apparently taking place after 1 year. In 1 adult a painful, disabling traumatic arthritis of the hip was healed by osseous fusion in 4 months. Additional patients upon whom this operation has been performed are showing every evidence of a similar high percentage of osseous fusion.

The Brittain ischiofemoral arthrodesis ideally combines an intertrochanteric osteotomy which allows temporary joint rest and an inferiorly placed strut graft healing occurs under compression stresses rather than tension stresses as in the iliofemoral operations.

RUDOLPH S. REICHER, M.D.

Blair, H. C., and Morris, H. D.: Conservation of Short Amputation Stumps by Tendon Section. *J Bone Surg*, 1946 28 427

The stump length of the forearm is measured from the insertion of the biceps tendon to the bone ends of the stump. The minimum stump length allowing the fitting of a forearm prosthesis and furnishing enough leverage to activate it is $1\frac{3}{4}$ inches.

When the elbow is flexed against resistance, the biceps stand out and similarly when the knee is flexed, the hamstrings become prominent. The effect is to crowd the prosthesis off the short stump; this inhibits the use of the prosthesis in flexion, especially in the upper extremity. The authors have found that by excising 1 inch of the biceps tendon at or near its insertion, approximately 2 inches in length of useful stump are gained. In short, below the knee stumps, excision of the fibula and section of the medial and lateral hamstrings allow a gain of approximately 2 inches of useful stump length. A functional stump length of $1\frac{3}{4}$ inches below the knee joint is usually considered the shortest which will allow the proper fitting of an artificial limb.

The authors have carried out the procedures described on 10 short forearm stumps and on 22 short below the knee stumps. Only 1 patient required reamputation at a higher level because of a severe flexion contracture of a below the knee stump. All other patients were fitted satisfactorily with prostheses.

VENKAY C. TUNNEY, M.D.

FRACTURES AND DISLOCATIONS

Maronneand, P. L.: Fractures of the Inferior Maxilla and Indications for a New Surgical Method of Treating Fractures: Osteosynthesis with Kirschner Wire (Considérations sur les fractures du maxillaire inférieur et les indications d'un nouveau moyen chirurgical de contention: le brochage). *J med Bordeaux* 1946 123 201

Holding up the bony fragments in fractures of the symphyseal region of the lower jaw bone by transversely placed and crossed Kirschner wires has already been described by others; however the author places the wires longitudinally along the ramus of the jaw and also uses the method for fractures of the angle and ascending ramus of the mandible.

The technique consists simply of placing a wheel of local anesthetic at the mandibular symphysis, denuding the bone for a distance of 1 cm., and passing the Kirschner wire backward within the substance of the horizontal ramus between the dental canal above and the lower edge of the jaw bone below. Upon reaching the fracture line the wire passes on into the posterior fragment which is maintained in place by an assistant. If, however assurance of the correct alignment of the fragments is desired a preliminary wiring of the fragment, or fragments to the superior maxilla (homomaxillary splinting) is done and this is removed after the Kirschner wire has been placed. The jaw is then simply bandaged or a plas-

ter splint is applied externally to immobilize the mandible. The method assures perfect reduction gets rid of the unpleasantness of the continuous mandibulomaxillary occlusion, permits a moderate amount of precocious mobilization (so favorable to callus formation) shortens the period of healing and does not require a secondary surgical intervention for removal of the apparatus of osteosynthesis.

The author does not wish to identify his method with the popular method of intramedullary plating which is not applicable to fractures of the mandible because of anatomical considerations.

JOHN W. BRENNAN, M.D.

Compers, E. L. and Schnurte, W. J.: Treatment of Congenital Dislocation of the Hip. *J Bone Surg* 1946, 28 555.

The most common cause of poor results in the treatment of congenital dislocation of the hip in children under 4 years of age is discontinuance of immobilization before an adequate hip joint is clinically and roentgenographically demonstrable. To be acceptable, the depth and slope of the superior acetabulum must be relatively normal, and the femoral head and acetabulum must fit accurately and articulate smoothly.

To avoid long periods of plaster immobilization, most surgeons have discontinued splinting when the hip joint seems stable. The hip joint may not redislocate but marked inadequacy of the acetabulum results in disability and possible redislocation later in life.

As the orthodontists reshape bones of the jaw by gentle pressure over long periods of time, so the ace-

tabulum and femoral head may be reshaped by months or years of corrective pressure. Fat and fibrous tissue obscuring the acetabulum will absorb if pressure is maintained long enough. To this end the authors use a modified Denis Browne splint with a long bar between the footplates to maintain abduction. This secures the constant pressure of the femoral head in the acetabulum without rigid immobilization. The patient is able to sit up, and may be taken out of the splint for bathing and graduated periods of freedom.

The routine of treatment as used for the past 3 years on 16 patients under 4 years of age, is outlined.

Position 1 Frog leg cast in 90 degrees of abduction for 3 months.

Position 2 Abduction spica cast for 3 months.

Position 3 Bilateral long leg plaster casts held widely apart and in slight internal rotation by a plaster strut, for 3 months.

Position 3b Denis Browne splint with long spreader bar for 3 months which is removed daily for the bath.

Position 3c Same as 3b but the splint is left off 1 hour each morning and afternoon with an additional hour of freedom per day added each week. The splint is kept on at night until the hip presents normal contours roentgenographically.

The case studies are illustrated by photographs of the positions and by roentgenograms, but it is too early for an end result study. However the authors believe that most congenital dislocations of the hip can be reduced, the reduction maintained, and a relatively normal joint developed by means of prolonged functional splinting.

FRANCIS E. BRECKENRIDGE, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Barone A. M.: Multiple Perthes Test for Segmental Occlusion of the Deep Veins. *J. Am. M. Ass.* 1946, 131: 1406

The author emphasizes the importance of determining the patency of the deep venous system before injection or ligation treatment of superficial varicosities. Perthes test for occlusion of the deep veins bases its conclusions on the physiologic actions of the skeletal muscles of the leg during walking. Perthes test consists of placing a tourniquet about the thigh just above the knee, sufficiently tight to compress the long superficial saphenous vein and prevent the reflux of blood into the distal saphenous system; the patient then walks vigorously or flexes and extends the knee repeatedly. The interpretation of the test is as follows: (1) if the varicosities collapse during the muscular activity the deep veins are patent, and the test is reported as negative; (2) if the varicosities do not collapse but become more distended and the patient notices pain or cramps in the leg with activity, obstruction of the deep circulation is present, and the test is reported as positive.

A positive Perthes test is sufficient proof of occlusion of the deep veins, but the author points out that a negative test may not always mean a competent deep circulation; such an instance may prevail in a segmental thrombosis. If an obstructing thrombus is present in a segment of a deep vein in the thigh, it is possible for the blood to make a detour around the thrombus by passing through a deep communicating vein below it into a superficial vein and then back into the deep vein through a communicating channel proximal to the thrombus. Therefore, an obstructing occlusion may be present in the deep vein and yet the varicose superficial veins will collapse on walking with a tourniquet above the knee (see diagram). In order to obviate such erroneous conclusions the author recommends the application of the tourniquet at 5 inch intervals from the knee to the groin as in this manner the level of the detour can be determined. Thus if the varicosities below the tourniquet collapse every time the patient walks with the tourniquet at different levels, there is no segmental thrombosis; but if a level is reached at which the distal veins remain distended and become more distended the tourniquet is constricting the detour level and preventing the flow of blood through the communicating vein into the superficial veins.

Cases which are suggestive of deep vein occlusion and therefore require the multiple Perthes test are (1) those with a history of thrombophlebitis or phlebotrombosis (2) those with a history of trauma especially fracture (3) those with a suspicion of deep vein occlusion as evidenced by pain

Fig. 1 (Barone.) Multiple Perthes test for segmental occlusion of deep veins.

and swelling (4) those with phlebographic evidence of obstruction and (5) those with an equivocally negative Perthes test.

The author emphasizes the necessity for ascertaining that the superficial venous dilatations are not compensatory to deep venous obstruction as failure to observe this phenomenon before instituting surgical treatment will result in undesirable and critical complications.

EDWARD H. CAMP, M.D.

McGowan J. M.: Cervical Rib; The Role of the Clavicle in Occlusion of the Subclavian Artery. *Ann. Surg.* 1946, 124: 71

The author attempts to throw more light upon the syndrome of the cervical rib and scalenus anticus muscle. This study is derived from 9 cases of cervical rib 3 of which required surgical treatment.

A review of the various theories presented in the past includes the theory of sympathetic hyperactivity from irritation of the sympathetic nerves which results in vasospasm. Jones Todd Telford and Blair incriminated the cervical rib alone as the predisposing factor of position of the thoracic girdle was recognized.

The importance of the scalenus anticus muscle was brought forth by Adson and Coffey and later the scalenus anticus syndrome as an entity *per se* was emphasized by Ochsner Gage and DeBakey. Judovich has implicated a narrowing of the costoclavicular space, whereas Wright believed that the nerves and blood vessels were pinched between the first rib and the clavicle. Aynesworth included the cervical rib as well as the first rib and also mentioned the possibility of trauma to the subclavian artery from excessive movement of the shoulder.

The symptoms produced may be either vascular or neurological, or both. The former are blanching, numbness, tingling, cyanosis, and coldness whereas the latter include radiating pain down the arm and occasionally into the neck and scapula, anesthesia, paresthesia and numbness, atrophy of the muscles supplied by the ulnar nerve, and finally trophic disturbances.

The irritative and destructive signs are the result of pressure, stretching, or friction of the brachial plexus and blood vessels between a cervical rib, fibrous band, or the scalenus medius and pectoreus muscles posteriorly and the scalenus muscle or clavicle anteriorly. The position of the ribs—either the cervical or the first thoracic—in relation to the shoulder girdle and the origin of the brachial plexus determine whether the structures will be put under tension, stretched, or pinched. If the rib is lateral the structure will be pinched between the rib and the clavicle, particularly when the shoulders are thrown back. A medially placed rib will press against the scalenus anticus muscle. In this group of cases any maneuver placing the scalenus anticus muscle under tension will produce or aggravate the symptoms, especially obliteration or diminishing of the pulse.

In only 1 case with a medially placed cervical rib was the Adson maneuver positive. The remaining cases revealed an obliteration of the pulse in the arm but not in the third portion of the subclavian artery which lies distal to the scalenus muscle. Thus the obliteration must have taken place where the artery passed between the cervical rib and the clavicle.

Mild cases may be alleviated by exercise tending to elevate the shoulder by strengthening the trapezius and levator scapulae muscles and instructions should be given to the patient not to throw back the shoulders. If surgery is indicated the scalenus anticus muscle is severed and a portion of the cervical rib is removed. The author believes that anterior scalenotomy alone would not be sufficient; however this procedure alone was not performed.

JACK L. WOOLFE, M.D.

Shumacker, H. B., Jr. and Carter, C. L. Arteriovenous Fistula and Arterial Aneurysms in Military Personnel. *Surgery* 94: 20-9.

The study comprises 245 arteriovenous fistulas and 119 aneurysms observed at the Mayo General Hospital, Galesburg, Illinois. The signs and symptoms were those usually described in these conditions except for the absence of evidence of myocar-

dial insufficiency in all but 2 patients. Generally the frontal cardiac area was demonstrably increased on roentgenographic examination in instances in which there was a large fistula, with the exception of lesions of the carotid vessels in which cardiac enlargement was usually absent. The correct localization of the aneurysm or fistula was generally easy and in only a few cases was an error in localization made. The most common difficulty arose in cases with lesions of the profunda femoral vessels in which the position, bruit and thrill could be eliminated only by compression of the overlying femoral as well as the involved profunda vessels. In other cases lesions of a branch close to the main artery were incorrectly localized to a larger vessel.

Arteriograms were useful in cases of intramuscular aneurysm without bruit or thrill, in cases in which there was uncertainty regarding the exact localization of the lesion, particularly when tests showed collateral circulation to be poor and in cases in which it appeared that the aneurysm was being "cured" by thrombosis. In the great majority of cases it was found that arteriograms were unnecessary.

The distribution of the lesions involved all the major arteries of the body except the abdominal aorta and the common iliac arteries. Nine patients had multiple aneurysms and fistulas. The problem of treatment was often complicated by the presence of associated injuries such as fractures and damage to the peripheral nerves. Thirty-three and eight-tenths per cent of the arteriovenous fistulas were complicated by nerve injury. In about half of these operative treatment was required, such as neurolysis or neurotomy. Sixty-one and three-tenths per cent of the arterial aneurysms were associated with nerve palsies of which two-thirds required operation. Most of the serious nerve injuries were associated with lesions of the great vessels of the upper extremity.

Of the various tests used for determining the adequacy of the collateral circulation in the limbs, the Matisa reactive hyperemia test was found most reliable and practical. The absence of pulses distal to an aneurysm or fistula in a limb which had maintained good circulation also proved an indication of adequate collateral circulation. The most useful sign which could be elicited at the time of operation was the maintenance of good color and warmth of the hand or foot during a prolonged period of accurate occlusion of the involved segment of the artery with a rubber shod clamp.

Since one of the most important factors in the development of adequate collateral circulation is arteriovenous fistula in the duration of the lesion, operation was usually not performed until the lesion was of 4 months duration or longer. The indications for early intervention were rupture (either external or subcutaneous) infection, severe myocardial insufficiency and associated severe nerve paralysis. The authors believe that repeated occlusion of the involved artery hastened the development of adequate

collateral circulation. Sympathectomy was utilized extensively to increase the collateral flow especially for axillary, femoral, and popliteal lesions. The results were generally good. However the only limb in which gangrene developed immediately after excision of a fistula had been sympathectomized. Similarly the only instance in which the ischemic paralysis followed operative cure of an aneurysm was one in which sympathectomy was performed at the conclusion of the operation.

The operative approaches were chosen to provide good exposure, but no incisions were used which followed the course of the vessels longitudinally across the axilla, the antecubital space, and the popliteal fossa, or which crossed normal skin creases of the neck and the groin.

Four operative methods were used for arterial aneurysms. When the sac was small and the neighboring nerves and vessels could readily be dissected free the entire aneurysm was excised. Intrasaccular ligation of the artery without excision of the sac was employed primarily for large aneurysms not associated with peripheral nerve lesions. When the aneurysm was closely adherent to nerves which could not readily be freed from it beforehand intrasaccular ligation of the vessels was followed by complete or subtotal excision of the sac. Proximal ligation of the affected artery was the method reserved for intracranial carotid aneurysms.

The operative technique usually used in the cure of arteriovenous fistulas was excision with quadruple ligation of the affected artery and vein together with ligation of branches which communicated with the fistula. In 33 instances the affected artery was preserved intact. Restoration of the artery was not feasible more often because the damage to the artery was often extensive, requiring excision of a portion which eliminated the possible use of such simple types of repair as ligation of the fistula or lateral suture. On the other hand, end to end suture or vein graft would have required the sacrifice of some important collateral branch which the authors considered unwise.

Cure of the aneurysm or fistula was achieved in all but 1 case, a large saccular arteriovenous aneurysm involving the right innominate and left subclavian vessels along with the arch of the aorta and superior vena cava. The majority of the patients showed no evidence of circulatory insufficiency after operation while at rest or with moderate exercise about the wards. Nevertheless, weakness and fatigability were frequently demonstrable after operative ligation of a main artery to the upper extremity, and intermittent claudication was common after interruption of a major artery to the lower extremity. Sympathectomy was performed in 34 cases of this type with only partial alleviation of the symptoms.

In the 33 cases of repair of arteries there were 6 failures. The other 27 cases showed no signs of arterial insufficiency after operation.

Among the 283 patients operated upon by the authors there were 6 major complications, 2 fatal

ities, 2 cases of gangrene, 1 temporary hemiplegia, and 1 ischemic nerve paralysis.

THEODORE B. MASSELL, M.D.

Elkin D. C. Cirsoid Aneurysm of the Scalp. *Ann Surg.* 1946 123: 591.

The author describes 4 cases of cirsoid aneurysm of the scalp encountered in the course of operations upon approximately 470 aneurysms and arteriovenous fistulas incident to wounds of warfare. When contributing arteries and outgoing veins form multiple anastomoses and become in reality a diffuse arteriovenous fistula the term "cirsoid" is generally applied. In one of these reported cases, the condition arose in the site of a pre-existing telangiectasia involving the scalp and ear and had as the more immediate etiological agent a long-continued irritation from wearing a helmet; the other 3 cases followed trauma to the scalp without any pre-existing vascular lesion.

Although methods of treatment are multiple, e.g., carotid ligation, multiple ligation of the lesion itself, obliteration with the galvanocautery, injection of sclerosing agents and surgical excision, the last method was considered more certain of cure and was the method of choice.

All of the patients were treated similarly; the principal artery or arteries leading to the lesion were independently ligated as a preliminary step. A scalp flap, horseshoe in shape and including galea, was then reflected to expose the lesion from the under side. Hemostasis was secured by finger pressure and by independently ligating and dividing each vessel as it was encountered in the incision. The main vessels including the central portion of the lesion were completely excised from the under side of the flap which was then replaced with interrupted silk stitches in galea and skin. EDWARD H. CAMP, M.D.

Moses, W. R. Ligation of the Inferior Vena Cava or Iliaic Veins. *N. England J. M.* 1946 235: 1.

The author reviews the history of operative interruption of the inferior vena cava. In summarizing the literature on the subject in 1937 Krotoski collected 48 cases of ligation of the vena cava, performed by 27 operators. In 1944 Homans reported 14 cases of surgical interruption of the iliac vein for venous occlusive disease of the lower extremities.

Whether medical or surgical therapy will prove to be the more satisfactory solution for the problem of treatment of pulmonary embolism depends on the information to be gleaned from several more years of experience. The evaluation of any therapeutic approach to the problem of phlebothrombosis must of necessity await the clarification of the diagnosis of its presence. Phlebothrombosis resembles no other disease so closely as it does cancer in that the most significant phase of the disease occurs during the period when the diagnosis is the most obscure.

The following indications on which the decision for ligation of the vena cava may be based have been tentatively accepted by the author: thrombophle-

itis of the pelvic veins with pulmonary emboli pulmonary embolism associated with prostatic tenderness of recent or presumably recent origin especially with demonstration of deep tenderness along the anterolateral region of the rectum reasonably conclusive evidence of pulmonary infarcts the source of which remains obscure despite diligent search and venous occlusion of the lower extremities that would otherwise be treated by interruption of the femoral vein alone. The conditions governing the last are as follows: cellulitis or lymphangitis of the upper thigh, infections of the groin or the finding of enlarged and tender inguinal or femoral triangle lymph nodes recurrent emboli following bilateral ligation of the femoral veins femoral phlebotrombosis with tense edema extending above the knee the operative finding of adherent clot on exposure of the femoral vein and acute thrombophlebitis extending into the upper thigh clinically with the presence of pulmonary embolism.

In the prevention and therapy of pulmonary embolism ligation of the inferior vena cava is related to interruption of the femoral vein not as a substitute but rather as a complement. The medical literature is replete with sizable case series proving that femoral ligations are safe, simple and responsible for a significant decline in the mortality from pulmonary embolism. There remain, however certain conditions under which low ligations do not suffice and higher ligations than those of the femoral veins seem the procedures of choice. Thrombophlebitis of the pelvic veins with pulmonary emboli cannot be prop-

erly handled with any surgical intervention less radical than ligation of the vena cava.

Ligation of the vena cava is comparable to ligation of either iliac vein, requiring no more anesthesia, exposure, technical skill, or time. For these reasons, the iliac approach has been entirely abandoned by the author.

The operative technique of ligation of the vena cava is described, and the incidence and etiology of postoperative edema of the extremities are discussed.

Abstracts of the case histories of the 13 patients who died and the essential data on the 23 who survived are presented. HENRIET F. THOMSON, M.D.

BLOOD; TRANSFUSION

Puyó Villafañe, E.: Intracardiac Transfusion (Gastrotransfusión Intracardíaca). *Sem. M.M., B. Ar.* 1946, 33, 874.

The author reports 2 cases of shock in which the patient received an intracardiac transfusion with a successful result.

The first case was that of a 34 year old soldier who had an operation on his knee and collapsed 5 hours later. Adrenalin and citrated blood were injected intracardially. The patient survived only for a few hours. The second case was that of a patient with a wound in his neck and an aneurysm of the subclavian artery who had collapsed. He was given 500 cc. of physiological solution intracardially and 300 cc. of blood with very good results. The patient survived the operation. WILLIAM E. RICKETS, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE POSTOPERATIVE TREATMENT

Bohmansson G., Rosenkvist H., Thorsén, G. and
Wilander O.: Clinical Experiences with Dex-
tran as a Plasma Substitute. *Acta chir scand*
1945, 94: 149.

Dextran is a polysaccharide of glucose molecules obtained as a special product in the manufacture of beet sugar. For intravenous use it is purified and its molecular weight is hydrolyzed down to about 100,000. It is used in a 6 per cent solution with a viscosity of 4.5 to 5.2. This solution when given to human beings, has a tendency to increase the sedimentation rate. No impairment of renal function was demonstrable on the basis of a careful check of the urinary output, specific gravity, excretion of sodium chloride, and urea clearance. Hippuric acid phosphatase, bilirubin and urobilinogen revealed no impairment of liver function. Erythrocyte leucocyte and thrombocyte levels were not affected. There was no sensitization due to repeated infusions. Transfusions, intravenous and intrasternal caused no local phlebitis, and paravenous leakage gave no severe pain. The increase in blood pressure following dextran was due to the increase in circulating volume. In every case of shock treated with dextran the rise in blood pressure was maintained for a satisfactory period of time. Oscillometric readings showed that dextran increased the strength of pulsation and also served to decrease the level of hemoglobin concentration in shock. About one-eighth of the infused dextran reaches the urine in 4 hours and the remainder is usually excreted in about 24 hours.

The reactions following the injection of dextran were mild—urticaria, chill, a rise in temperature, muscular pains, headache, and lumbar pain occurring occasionally.

BENJAMIN G. P. SHAFROFF, M.D.

Evans, J. A. and Boller, R. J.: Subcutaneous Heparin in Anticoagulation Therapy. *J Am Med Assoc* 1946 131: 879.

The authors report the recent experiences at the Lahey Clinic, Boston, Massachusetts, with the subcutaneous administration of heparin in anticoagulation therapy for cases of postoperative venous thrombosis. In the last 3 years and 10 months only 133 such cases developed in approximately 20,000 major surgical procedures. In 8 of these femoral ligation was performed, without further venous sequelae. This operation was reserved for cases of ambulatory recurrent calf phlebotrombosis with one or more benign pulmonary emboli or postoperative cases in which a second operation had to be performed. In the other 125 cases treated with anticoagulation therapy there was only 1 death. During the same period, approximately 40 patients died of sudden pulmonary embolism without warning.

The characteristic effect of dicumarol on clotting—a drop in the prothrombin percentage—is achieved in from 2 to 5 days. During the period of lag heparin has been given to prolong the coagulation time. Within the last 9 months the intravenous drip method of administering heparin has been discontinued and replaced by the more desirable method of subcutaneous injection. In this procedure Pitkin's menstremum (18% gelatin 8% dextrose, and from 1 to 1.5% acetic acid in distilled water) which releases water soluble drugs slowly is utilized as a vehicle for the heparin.

The Pitkin's menstremum is supplied in 1 c.c. ampules containing 100 mgm. of heparin and 2 c.c. ampules containing 200 mgm. of heparin. Either ampule may be had with vasoconstrictors added—10 mgm. of ephedrine and 1 mgm. of epinephrine. The authors regard the following as the most effective dosages for patients under 150 pounds: 1 c.c. without vasoconstrictors and 1 c.c. with vasoconstrictors given simultaneously with the first dose of dicumarol and for patients over 150 pounds: 1 c.c. without vasoconstrictors and 2 c.c. containing vasoconstrictors. Daily prothrombin percentage determinations guide the dicumarol therapy and daily coagulation times, the heparin/Pitkin therapy. The dose is repeated if the coagulation time returns to normal before the dicumarol has lowered the prothrombin time to at least 69 per cent. An initial dose of 200 mgm. of dicumarol is given to patients under 150 pounds and of 300 mgm. to those over 150 pounds. A daily maintenance dose of 100 mgm. is given whenever the prothrombin is over 65 per cent.

Of the 18 patients in the author's series receiving heparin/Pitkin therapy, 9 were given no vasoconstrictor whereas the other 9 received it. The first group with no vasoconstrictors, showed an increase in coagulation time within 2 hours. Three patients responded in the first hour. The maximal effect took place between 12 and 24 hours later and the average duration of the effect was 41 hours. The second group showed approximately the same time of onset of effect and time of maximal effect. However there was a greater duration of the effect in these cases the average being 61 hours. When the heparin/Pitkin therapy was given in a ratio of 200 mgm. with vasoconstrictor to 100 mgm. without, a marked prolongation of effect was attained up to 108 hours in 1 instance. This result is more to be desired in cases in which heparin is being given alone than in those in which it is merely given during the latent period in dicumarol therapy.

Occasional side effects of heparin/Pitkin administration are mild and usually require no treatment. They consist of local pain, swelling, and tenderness. Symptoms of palpitation and mild vertigo caused by the vasoconstrictors subside within an hour without treatment.

The authors conclude that heparin administered subcutaneously in Pitkin's menstruum, with or without vasoconstrictors, is an effective agent in anticoagulation therapy. B F LOOMSBURY M.D.

Bauer G : Heparin in Venous Thrombosis. *J Am. Med. Ass.* 1946, 131: 196

In the summer of 1940, a new method for the treatment of thrombosis of the deep vein of the leg was introduced at the Mariestad Hospital in Sweden. In preliminary investigations, phlebograms were performed on nearly 600 patients. In 246 of these patients studies were made of acute deep thrombosis. In another equally large group the chronic stage of the disease was studied. About 130 phlebograms and dissections were made to ascertain the normal anatomy of the veins of the leg.

It is now almost generally agreed that thrombophlebitis is a primary disease of the wall of mainly the subcutaneous veins, secondarily followed by thrombotic obliteration. On the other hand in the deep veins of the leg the clotting of the blood is the primary factor and only secondarily the wall of the vein becomes involved. Acute thrombosis of the deep veins, or phlebothrombosis are the terms for this process. About 250 phlebographic studies have shown that the process begins with a thrombus arising in a muscle vein and projecting into one of the larger veins where it becomes the starting point of a deposition thrombus the latter continues growing upward in the direction of the blood stream for 40 to 50 mm. gradually occluding the entire lumen.

The thrombus is anchored only at its lowermost end far down in the lower part of the leg. Within 24 to 48 hours the thrombus either gives rise to an embolus or more often, it fills completely the femoral vein and becomes attached to it giving rise to phlegmasia alba dolens. This course was proved by phlebography which also revealed an occurrence of thrombosis in the other leg in at least 30 per cent of all untreated patients. Recanalization of the thrombosed veins seldom occurs.

For the rest of the patient's life the drainage of the venous blood from the lower part of the leg is taken care of by the saphenous and an accessory system of subcutaneous veins. A mild state of venous stasis occurs and due to overloading the superficial veins undergo degeneration and distention and their valves become defective. This in turn increases the stasis in the lower part of the leg and leads to induration and ulceration of the skin. Leg ulcers, thought to be due to varices, were found in 80 to 90 per cent of cases, to be due to deep thrombosis, and therefore the term post thrombotic ulcer is proper. Deep thrombosis has unfortunately led to permanent swelling of the leg in more than 90 per cent of patients to indurative lesions, and in about 80 per cent to leg ulcers. Early diagnosis is highly desirable in order to prevent fatal pulmonary embolism by vein ligation or anticoagulant therapy. The latter if used early, stops the thrombotic process in the lower leg thereby preventing late thrombotic sequelae.

None of the early clinical signs, such as rise of pulse, of temperature or swelling or tenderness in the calf are absolutely indicative of thrombosis unless confirmation is had by phlebography. No patient was treated by the author without x-ray confirmation of the diagnosis. The interpretation of x-ray pictures does not give rise to difficulties, provided careful technique is observed, and some experience is at hand.

In an initial group of 29 cases in which phlebography disclosed incipient thrombotization of the lower part of the leg no heparin therapy had been used as yet. In 24 of these cases, spread to the femoral vein and the development of phlegmasia alba dolens were shown. Pulmonary embolism occurred in 11 cases, and proved fatal in 5. In 10 cases the thrombosis was bilateral. High femoral vein ligation was performed in 5 cases with pulmonary infarction.

The knowledge of the late results of thrombosis, when the popliteal and femoral veins were involved and put out of function was a warning against the continued use of femoral vein ligation and it was therefore decided to try heparin.

The prophylactic use of heparin was ruled out, and its use in fully developed thrombosis did not appear promising. Results with heparin in early thrombosis were favorable and the entire course of the disease was changed: there was no spread of thrombosis, fever, pain and swelling subsided in a short time and the patients left their beds in less than a week. The treatment consisted of (1) early diagnosis (2) immediate intensive heparinization (3) movement of the leg from the beginning (4) getting patient out of bed as soon as acute symptoms disappear and before the termination of heparin injections.

Heparin was administered by intermittent intravenous injections. 150 mgm. of heparin was given as the initial dose followed by 1 or 2 equal injections every 4 hours the last dose given late at night. On the following day, 3 or 4 injections were given with early morning and night doses of 150 mgm. and 1 or 2 mid-day doses of 100 mgm. After a few days the temperature returned to normal and swelling and palpation tenderness disappeared. The patient was then allowed out of bed and the heparin dose was reduced to 100 mgm. twice daily and was discontinued after 1 or 2 days. When leaving bed, the patient was provided with an elastic bandage or a Unna's paste stocking covering the foot and lower part of the leg for a period of 2 to 3 weeks.

It was found to be of utmost importance that the patient get out of bed before heparinization was terminated. In one case, for instance, disregard of this rule apparently resulted in death. It should be stressed that when heparin is no longer being administered the patient is on the following day totally unprotected against fresh thrombosis. The average stay in bed was 4-7 days after starting heparin therapy as compared with 40 days in the control group.

Getting out of bed may not be feasible in some cases, as in fractures of the lower extremities. Pro-

tracted heparin treatment was then used and tension and relaxation exercises were performed in bed even under a cast. In the protracted heparin treatment, heparin was given every other evening during the second week and every third evening for another week, and then discontinued. It was assumed that the body had by then adapted itself to the new condition. In none of the 32 patients thus treated was any recurrence observed.

In cases with massive pulmonary embolism larger doses were used i.e. 150 mgm. every 4 hours. An antispasmodic was also given.

If a phlegmasia alba dolens was already manifest as in patients previously treated by practitioners treatment was materially the same. In some cases response was fast in others somewhat larger doses and more prolonged treatment was necessary.

During a period of 5 years from 1940 to 1945 209 cases of acute thrombosis of the deep veins of the leg were treated. In almost all cases the diagnosis was verified by phlebography. In a comparative series of 264 cases of thrombosis observed during a period of 10 years there were 47 deaths. On the other hand of the treated patients, only 3 out of 209 died thus the mortality after heparin treatment dropped from 18 per cent to 1.4 per cent. Likewise, the mortality from pulmonary embolism dropped from 0.3 to 0.018 per cent. The following comparison is made of the thrombotic material at Mariestad Hospital Sweden, during a 10 year period when an old fashion treatment was used and a 5 year period when heparin treatment was used.

	1940-1945 Conservative treatment	1940-1945 Heparin treatment
Number of patients admitted	15,628	16,495
Number of thrombotic cases	264	209
Fatal embolism	47	3
Mortality among thrombotic cases	18%	1.4%
Total mortality from thromboembolism	0.3%	0.018%

Of these 29 patients (two fifth) were admitted because of thrombosis which had been contracted in their homes or at other hospitals, but had not received any treatment.

Contrary to general belief no intra abdominal subcutaneous, or other serious bleedings were encountered with heparin except for hematuria which was seen in 3 cases lasting only 2 days and was not followed by any renal irritation. It passed off without necessitating discontinuation of the heparin

regime or even reduction of the dose. In 2 cases a mild bleeding into the knee joint occurred after operation for a lacerated meniscus. Thus there appears to be no contraindications to the use of heparin, and diseases of liver kidney or other parenchymal organs are not badly influenced. Puerperal bleeding was not affected and existing traumatic hematomas were not enlarged.

It is highly probable that a large majority of heparin treated patients will escape troublesome after effects which have been regularly observed in conservatively treated thrombotic patients who develop permanent leg swelling and later brown induration and ulcers.

ARTHUR J. LERSSER, M.D.

ANTISEPTIC SURGERY TREATMENT OF WOUNDS AND INFECTIONS

Perez, M. Experimental Study of the Pathogenesis of the General Syndrome of Burns (*Ricerche sperimentali sulla patogenesi della sindrome generale da scottatura*). *Arch. Ital. chir.* 1945 67 343

The pathogenesis of the general syndrome of burns was studied in dogs. Under ether anesthesia the sciatic obturator and femoral nerves were resected. In order to avoid traumatic shock, novocain was injected into the nerve trunks before they were severed. A segment of each nerve, 2 cm. long was resected and in addition a periaxillary sympathectomy of the femoral artery was performed. In one series of experiments the procedure was supplemented by a bilateral lumbar sympathectomy done via the transperitoneal route. Ten days later a burn was produced by immersing one of the lower extremities in hot water.

The general condition of the pulse, blood pressure, respiration, body temperature, and blood picture of the animals was recorded. The author concludes from his observations that denervation of the burned extremity does not modify the general syndrome of a burn. Phenomena related to the increase of the concentration of the blood in the capillaries are of a reflex origin.

The general syndrome of a burn is due to the entry of toxins from the burned area into the circulation. Such toxic substances affect chiefly such organs as have antitoxic functions. JOSEPH K. NARAY, M.D.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Esguerra Gomez, G: Roentgenography and Tomography of the Larynx (Radiografía y tomografía laríngeas) *Boi. Clin. Méjico* 1946 8 38.

The author makes a comparison of the roentgenographic and tomographic procedures in the diagnosis of diseases of the larynx in 5 cases. He concludes that both procedures are very useful, and that their associated use gives better information than each procedure alone. WILLIAM E. RUCKENR, M.D.

Gershon-Cohen J: The Phantom Nucleus Pulposus. *Am. J. Roentg* 1946 56 43

The author reports 3 cases in which he noted a slitlike region of decreased density within the intervertebral space between the fifth lumbar and first sacral segments and 1 case in which such a region was found also between the fourth and fifth lumbar vertebrae. He believes the appearance ascribable to a "phantom nucleus pulposus," i.e., a vacuum in the intervertebral disc resulting from loss of the nucleus pulposus as hypothesized by Knuutson in 1942.

Each of these patients had sustained an injury many years earlier which had resulted at once in low back pain severe enough to incapacitate the patient for several weeks in the absence of positive neurological signs or of evidence of fracture or dislocation. Two of the patients had had occasional recurrence of the low back pain. Each of them on recent physical examination showed slight limitation of motion at the lumbosacral joint without other signs but there was roentgen evidence in each case, in addition to the phantom nucleus, of from minimal to moderate subchondral osteosclerosis localized to the lumbosacral region and associated with only slight narrowing of the intervertebral space.

The author believes that these localized hypertrophic osteoarthritic changes point to old injury in the affected region, and suggests that the phantom nucleus is another residuum of the injury at the time of which loss of nuclear substance presumably took place through a defect in the cartilage plate due to rupture of the annulus fibrosus. He believes it may prove a useful diagnostic sign of such disc injury in cases too recent to show accompanying subchondral osteosclerotic changes.

LESLIE DONALDSON, M.D.

Epstein, B. S., and Davidoff L. M: The Use of Laminagraphy with Encephalography in the Diagnosis of Midline and Subtentorial Brain Tumors. *Am. J. Roentg* 1946 53 675.

The authors recommend the use of laminagraphy as a routine procedure in pneumoencephalographic study in the diagnosis of midline and subtentorial brain tumors. During the past 2 years over 100 laminagraphic examinations were performed. The

findings of pneumoencephalogram and of laminagraph examinations of 30 controls and 15 cases which had tumors encroaching on the midline structures were compared in a table to demonstrate the superiority of laminagraphic visualizations over that of encephalograms. The usual standard exposure of the skull are taken before laminagraphic examination. The technique consists of taking a center or laminagraph and cuts 1 cm. to the right and 1 cm. to the left of the midline with the head positioned as for a lateral roentgenogram. Other studies are made as required by the individual patient. The structures which have been more satisfactorily visualized (Fig. 1) are the third ventricle, the aqueduct of Sylvius, the fourth ventricle, and the cisterna pontis.

The roentgenological localization of tumors of the midbrain, pons, cerebellum and adjacent structures rests on the effect of these on the midline structures as visualized by means of gas. The differential diagnosis between posterior fossa or midbrain tumors and inflammatory lesions including the aqueduct of Sylvius or the foramina of Magendie and Luschka may be very difficult, and often depends on adequate visualization of these structures. The basic criteria are filling or nonfilling of the ventricles, ventricular displacement or dilatation, and the demonstration of intraventricular shadows. Intraventricular tumors may arise from the ependymal linings (ependymomas) from the neuroglia close to the ventricle (gliomas) or from the choroid plexus (papillomas). Colloid cysts, which seem to occur only in the third ventricle, may spring from the paraphysis. Meningiomas may arise from the tela choroidea. They may manifest themselves roentgenologically as both intraventricular defects and displacement of the ventricles. Absence of filling of the third ventricle with adequate visualization of the lateral ventricle is considered strongly suggestive of intrinsic disease, but nonfilling of the fourth ventricle is much more difficult to evaluate. Lateral displacement of the third and fourth ventricles by supratentorial masses such as low parietal or temporal lobe tumors must not be confused with intratentorial or midline masses.

Tumors arising from neighboring structures may invaginate into the adjacent air filled structures. Among these are Rathke's pouch tumors, choroidal tumors, pinealomas, aneurysms of the circle of Willis or its main branches, gliomas of the basal ganglia and the quadrigeminal plate, and suprasellar or olivary groove meningiomas. Adamantinomas completely blocking the third ventricle have been described.

Stenosis of the aqueduct of Sylvius on a congenital, inflammatory or obstructive basis must also be considered when this structure is not visualized during pneumoencephalography and when the lateral and third ventricles are dilated. Hydrocephalic dilatation of the anterior aspect of the third ven-

Fig. 1 (Epstein and Davidoff) A, Lateral roentgenogram of the skull reveals atrophy of the dorsum sellae. The floor of the sella cannot be identified. B, Lateral ventriculogram shows moderate dilatation of the lateral ventricles. A soft tissue mass protrudes into the cisternae chiasmaticus and interpeduncularis from the region of the dorsum sellae. The third and fourth ventricles are poorly outlined. The sella is the same as noted in A. C, The lateral midline laminogram reveals the fourth ventricle in its normal position. The third ventricle is not seen. The disappearance of the floor of the sella turcica is strikingly portrayed, and the soft tissue tumor occupying the sphenoidal sinus is readily apparent. The anterior wall and floor of the sphenoid bone are intact. D Off-center laminogram outlines the entire third ventricle and the upper aspect of the aqueduct of Sylvius. The fourth ventricle is not seen on this laminogram. A chromophobe adenoma of the pituitary was found at operation.

resulting in enlargement of the sella turcica must be borne in mind when the differential diagnosis of intrasellar tumors is considered. Inasmuch as the anterior wall of the third ventricle is thinnest,

dilatation of that structure may cause it to balloon downward and forward. It then exerts pressure on the sella and produces enlargement and atrophy. Cerebellar tumors arising from the midline, such as

hemangioblastoma may displace the aqueduct of Sylvius anteriorly. Tumors arising from its inferior aspect may produce dilatation of the aqueduct as well as of the anterior portion of the fourth ventricle while tumors springing from its superior surface may result in dilatation of the aqueduct and compression of the fourth ventricle. A shift of the fourth ventricle to either side may aid in lateral kinking. Intraventricular tumors may be visualized although the cavity is not obliterated.

Pontine tumors may be diagnosed pneumocephalographically by dorsal displacement of the fourth ventricle and aqueduct and narrowing of the cisterna pontis as the result of a mass within the pons. From the roentgenographic viewpoint the lagorous cysts on a qualitative evaluation of these structures. Cerebellopontine atrophy results in an increase in the size of the neighboring cisternae. When present it may be diagnosed because of the dilatation of these structures as represented pneumocephalographically.

Six case reports illustrate the myelographic visualization of the cisterna pontis and fourth ventricle by laminography versus the lack of visualization by cephalography were presented.

FRANK H. J. M.D.

Scott W. G. Radiographic Diagnosis of Prolapsed Redundant Gastric Mucosa into the Duodenum, with Remarks on the Clinical Significance and Treatment. *Fed Med J* 4: 147

The author believes that prolapse of gastric mucosa into the duodenal bulb is a fairly common condition.

This condition occurred in 24 (104%) of 23 patients in which roentgenological examinations of the upper gastrointestinal tract were made. These examinations were made in a Naval Hospital to which patients with gastrointestinal lesions were referred. Three cases were proved by operation. Additional cases not included in this series in which the condition was seen at operation are described.

The principal symptoms in these 24 cases were: (1) flow, (2) intermittent epigastric distress, (3) epigastric pains (24), relief from food (26), sense of fullness (24), belching and heartburn (26) and nausea and vomiting (24). Most of the patients had severe reflux symptoms.

All roentgenological examinations were positive. The findings were: (1) prolapse of the mucosa into the duodenum (24), (2) a diverticulum (1), (3) a diverticulum (1), (4) a diverticulum (1).

The roentgen diagnosis is complete mainly of the characteristic features of the condition. The condition is like the diverticulum in the base of the duodenal bulb, which must not be confused with the diverticulum of the bulb proper.

Differential diagnosis must also be made between gastric ulcer (clinical grounds) and the prolapsed redundant gastric mucosa and hypoplasia of the duodenum, hypertrophy of the pyloric muscle (clinical type) hypertrophy of the pyloric muscle (clinical type) of the duodenal bulb with a diverticulum of the duodenum.

The recommended treatment is surgery (excision and pyloroplasty) in severe cases, especially those with bleeding and anemia, and medical treatment (with diet and drugs) in mild cases.

FRANK H. J. M.D.

MISCELLANEOUS

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Peters, F. M. A Disease Resulting from the Use of Pneumatic Tools. *Occup. M.* 1946 2 55

Blood vessel disturbances, affections of muscles with atrophy and injuries to the bones and joints have been observed in workers since the introduction of pneumatic tools into French mines in 1839. Vibration was found to be the primary causative factor and it has been shown that the critical vibratory rate for the onset of this condition is between 2,000 and 3,000 revolutions per minute.

The author presents a detailed study of 29 workers who developed disturbances after an average interval of 19 weeks, following the use of pneumatic tools capable of developing 25,000 revolutions per minute. Of about 1,000 people employed on the production of B 29 bombers, 116 presented themselves with symptoms which were markedly different as compared to those previously reported. Only that hand holding the tool was affected.

The pain was constant rather than intermittent and was worse in those fingers most intimately in contact with the tool. Most workers experienced radiation of pain to the arm or shoulder and all noticed a stiffness and weakness in the hand and the fingers. None noticed a change in color but most of them experienced swelling. Cold seldom accentuated the symptoms. Most of the patients exhibited various degrees of anxiety about the condition and had become nervous and hostile.

Although there were no reflex changes, most of the patients exhibited abnormal sensory and neurologic findings in that portion of the hand in closest contact with the tool. Blood pressure, arterial pulsation and oscillometric readings were all within the range of normal. The finger pulse volumes as recorded by a plethysmograph revealed abnormally low pulsations, indicating a predisposition to vasomotor disturbance. A thermocouple was used to measure the temperature and a marked lowering was discovered in the affected fingers. Microscopic study of the capillaries in the nail bed revealed morphologic changes in most instances with a decided decrease in number of capillary loops. The roentgenological and laboratory findings were practically always within the range of normal.

Medical and physical therapy have not proved encouraging, neither has preganglionic section of the thoracic sympathetic chain. Therefore prophylaxis is at present the only rational approach viz. (1) limitation of vibration under the critical level (2) dampening the vibration (3) limitation of the length of use of the tool and (4) mechanical devices to hold the tool.

The author suggests that fatigue may appear if the capillaries are subjected to many rapid repeti-

tive blows and that if these continue unabated death of the tissue itself may eventuate.

DAVID H. LYNN, M.D.

Illrah, H. L., Feller, H. L. and O'Neill, C. B.: A Study of the Diffusion of Penicillin Across the Serous Membranes of Joint Cavities. *J. Lab. Clin. M.*, 1946 31 535

Many joint infections are known to be caused by bacteria sensitive to penicillin. A study was made in order to determine penicillin exchange between blood and joint fluid as a prerequisite for the treatment of purulent arthritis.

Penicillin was injected into the knee joint or administered systemically. Assays were made on joint fluid and serum in order to determine the rate of diffusion across the serous membrane of the joint. Some patients received fever treatment during this procedure. The patients studied had rheumatic fever, rheumatoid gonococcal and other pyogenic arthritides. One hundred cubic centimeters of physiologic salt solution was injected into the knee joint and reaspirated for penicillin assay. No difference was found between sodium and calcium salts of penicillin G, calcium salts of penicillin X, or sodium crystalline penicillin. Penicillin was given by mouth in tablet doses of 100,000 units every 2 hours by continuous intravenous infusion of 100,000 to 500,000 units for periods of from 6 to 18 hours and by intermittent injection of 20,000 to 80,000 units every 2 hours or 25,000 to 30,000 units every 3 hours or 50,000 units every 6 hours or 200,000 units of penicillin in 20 to 50 c.c. of physiologic salt solution were injected into the knee joint.

If 30,000 to 200,000 units of penicillin were given into the knee joint, penicillin was found present in the knee fluid in from 24 to 120 hours depending on the dose. One hour after each injection penicillin was found present in the blood and was maintained at nearly constant levels throughout the period of observation. The concentration varied from 0.095 to 3.12 units per cubic centimeter. The knee fluid concentrations for from 12 to 24 hours were from 10 to 40 units per cubic centimeter. Only patients with secondary arthralgia showed no evidence of absorption of penicillin from the knee joint.

With extra articular administration of penicillin (oral or parenteral) joint concentrations from 0.095 up to 0.078 were found. The amount of penicillin which diffused into the joint cavity was varied and independent of serum concentrations. The diffusion into the joint occurred rapidly, from fifteen minutes after parenteral injection. Fever therapy did not affect the exchange of penicillin between blood and joint. The joint fluid concentrations of penicillin obtained with systemic administration of the drug are frequently insufficient to control the infection. Similarly insufficient amounts of penicillin are ab-

aspirated from the joint space into the blood stream to care for other sites of infections. It thus appears that in the presence of pyogenic arthritis, intra-articular treatment has to supplement systemic administration.

The local effect of penicillin on serous membranes has been known to be followed by a pleocytosis, and was found to increase the white blood count in the joint fluid for a period of about 48 hours following local injection.

ARTHUR J. LEASE, M.D.

Larsen, B. B.: Pilonidal Cysts and Sinuses: A Technique for Excision and Primary Closure. *A. M. S. J.* 1946 123 1090.

This report concerns 225 consecutive cases of pilonidal cysts operated on by the various officers and residents in Surgery at the A. F. Regional Hospital, Trux Field, Madison, Wisconsin. Since bacterial cultures demonstrated the pilonidal wounds to be sterile at the time of block excision, it was

reasonable to expect primary closure to be effective. The results are impressive.

Primary union occurred in 96.9 per cent of the cases, and only 1.2 per cent of these were accompanied by minor separation or infection. The few cases that healed by secondary union usually had presented either recent acute inflammation or profuse chronic drainage and in no instance did more than half of the wound break down. Two hundred and twenty of these cases were followed up for an average of 14 days after surgery and it was found that 87.6 per cent remained healed. None of the others presented a true recurrence of the pilonidal cyst. Moreover, the infection was readily controlled and never involved the deep portion of the wound where a "dead space" is most likely to occur.

In evolving a standardized surgical technique, emphasis was placed on several factors. Acutely inflamed cysts were allowed to "cool off" for 2 or 3 weeks under the usual conservative management. Low spinal anesthesia was used in all cases when contraindicated. Methylene blue in peroxide was injected into a sinus and the elliptical incision was carried laterally far enough to include all involved tissue. It was believed that wide defects could be closed without marked tension if the underlying subcutaneous tissue was properly built up. Undemaing of the wound edges was scrupulously avoided and the creation of muscle flaps was deemed ill advised.

Closure was performed in layers with a "slit technique" but with #40 cotton, because it produced less wound reaction as compared with catgut. Without including the sacral fascia, the deepest layer of sutures was placed at that level where the fat could be approximated without undue tension. Although this occasionally left a dead space, this was thought to be less serious than placing fat under tension. Usually 2 rows of sutures were sufficient to build up the more superficial subcutaneous fat, attention being exercised to avoid overlapping of the skin edges and to keep the topmost row of sutures from being placed too close to the skin. The skin sutures were placed carefully so as not to penetrate into the subcutaneous tissue as an additional safeguard against bacterial invasion, as this is the most likely mode of postoperative contamination. Because of its hygroscopic as well as its bacteriostatic properties, crystalline sulfanilamide was dusted on the closed incision but not into the open wound. Zinc stearate powder was subsequently substituted after 72 hours.

DAVID H. LEE, M.D.

Sirtori, C., and Zorzi, G. C.: Histogenetic Study of Adenolymphomas (Considerazioni istogenetiche sugli adenolinfomi). *T. med.*, Milano, 1945, 31 62.

Adenolymphomas are made up of epithelial and lymphoid tissue in varying proportions. They are relatively rare and various names have been given to them in cases with little lymphoid tissue and multiple cysts the name of lymphomatous adenocystoma is to be preferred. They are almost always located in the lateral region of the neck and the parotid gland.

Fig. (Larsen) a, The area is draped with wet towels. The bottom towel is clipped to the skin to protect the field from contamination. b, The block excision must assure a thorough removal of the cyst. Undermining should be avoided. c, Care is taken to place the bottom row of sutures at a level where the deep tissue can be approximated with out undue tension. The sacral fascia is never included in the deep suture layer. (Courtesy of J. B. Lippincott Co.)

are benign and grow slowly and rarely reach a very large size. They are enclosed in a connective tissue capsule and histological examination shows them to be made up of alveolotubular and cystic structures with walls of prismatic epithelium hurried in abundant lymphoid tissue.

A typical case is described in a man of 40 with a tumor at the angle of the jaw which in the course of a year reached the size of a small filbert. It was sharply circumscribed with a smooth surface and a soft pasty consistency movable on the underlying tissues and painless. Histologically it showed lymphoid tissue with germinative centers and epithelial tissue forming tubular and cystic complexes. The epithelium which bordered the cystic and tubular structures was prismatic, sometimes simple but more often stratified and in rows the cells had an acidophil cytoplasm and a spherical nucleus which stained deeply. No active karyokinesis or atypical cells were seen. In the lumen of the tubes there was sometimes an amorphous substance which was markedly eosinophil and contained cellular detritus and pyknotic nuclei. The lymphoid tissue which formed the stroma of the tubules had the same structure as that of the lymph glands. The germinative centers were not very numerous. The epithelial and lymphoid tissues were distinctly separated from each other by a membrane and there was no intermingling to indicate a possible metastasis from the one form of tissue into the other.

The various theories as to the origin of these tumors are discussed. The theory that they are derived from aberrant rests of salivary glands is rejected. The author believes they are branchiogenic tumors in the broadest sense of the word with a structure similar to that of the tonsils they are derived not only from the third branchial cleft but also from the other clefts. AUDREY G. MORGAN M.D.

GENERAL BACTERIAL, PROTOZOAN AND PARASITIC INFECTIONS

Pupo, J. A.: Clinical Study of Leishmaniasis Ameri-
cana of the Skin—*Leishmania Brasiliensis*—
Vianna 1911 (*Estudo clinico da leishmaniose tegu-
mentar americana—Leishmania brasiliensis*—Vianna
1911) *Rev Hosp Clin* 1946 1 113

A classification is given of the forms of leishmaniasis. The skin forms include the initial papulovesicular the papulofollicular the tuberculous, the vegetating the nodular and the ulcerous. The mucous membrane forms affect the nose, mouth and laryngopharynx and may be propagated to the maxillary sinuses. The lymphatic forms include nodular and follicular lymphangitis and lymphadenitis. There are combined cutaneous and cutaneous lymphatic forms. This disease may cause complications such as sinusitis osteomyelitis osteolysis tropical ulcer, skin and mucous membrane myiasis erysipelas and elephantiasis nostras.

In general, the disease begins with a papule or nodule which ulcerates and becomes covered with a

crust the removal of which causes bleeding. It may extend rapidly and cause extensive destruction of tissue but it may last for years without causing serious damage to the general health. In some stages it may be confused with syphilis blastomycosis or lupus vulgaris, but differentiation is not particularly difficult. A fusospirillary infection may give the ulcers the typical picture of tropical ulcer. In this case the differential diagnosis can be made by means of the Montenegro reaction. General treatment with eparseno heals both the conditions. Local treatment for the fusospirillary symbiosis is given with solutions of sodium hypochlorite, potassium permanganate or chromic acid or bismuth salts in the form of salves associated with salol and camphor. The larvae of flies may infect the ulcers of leishmaniasis and cause great destruction of the tissue and serious complications. The myases may be treated with salves and powdered calomel or water saturated with chloroform. Erysipelas is one of the most frequent complications of nasal leishmaniasis causing a chronic edema and elephantiasis nostras of the eyelids.

The various forms of leishmaniasis are described the descriptions being based on hundreds of cases seen by the author. Ninety nine illustrations are given which constitute a very valuable part of the article and give a clearer picture of the different forms of the disease than could be given by verbal description alone. AUDREY G. MORGAN M.D.

SURGICAL PATHOLOGY AND DIAGNOSIS

Roskam, J.: Bleeding Time in Human Beings; Its Utilization for Diagnostic and Pharmacodynamic Purposes (*Le temps de saignement humain. Son utilisation à des fins diagnostiques et pharmacodynamiques*) *Rev belge sc. med.*, 1945 16 157

The author used a slightly modified Duke's method of measurement of the bleeding time and gives an exact statistical evaluation of his results.

A close correlation was found between the bleeding time of the right and left ear at a room temperature of about 20°C. However the bleeding time varied

Fig. 1. (Roskam)

considerably from $\frac{1}{2}$ minute to $3\frac{1}{2}$ minutes according to the site of the incision in the ear lobe. Therefore an average should be obtained by making 5 incisions in the ear lobe (Fig. 1).

Two hundred normal subjects were examined in this manner and the average bleeding times and statistical standard deviations were calculated. It was found that all medium bleeding times exceeding 3 minutes should be considered pathological.

ARTHUR J. LESSER, M.D.

Addis, T., Barrett, E., Lew W. Poo L. J., and Others: Danger of Intravenous Injection of Protein Solution after Sudden Loss of Renal Tissue. *Arch. Int. M.* 1946 77 54.

In cases of shock there may be a sudden loss of effective renal tissue because for a time the kidney does not get enough blood more so valued deprivation sometimes occurs after transfusion reactions and there are instances of anatomic as well as functional loss, for instance when part of the kidney is destroyed by shell fragments, and when glomerular nephritis and symmetrical necrosis of the cortex the majority of the nephrons in a short space of time may become functionless and many may be irrevocably destroyed.

For each of these situations there is a specific treatment dependent on knowledge of the causative mechanism, but in all except the most transitory instances of functional loss, the authors believe that the work demanded from the remaining renal tissue should be reduced.

After removal of three-quarters of the total renal tissue from young rats there were no deaths when no protein was taken, but as the amounts of protein consumed increased there was an increasing number of deaths from uremia.

In the survivors there were no signs of renal failure when no protein was taken, but as the consumption of protein increased the concentrations of urea and creatinine in the serum rose toward uremic levels, although at the same time the rates of urea excretion, of urea clearance of work accomplished, and of new renal tissue constructed were all augmented. This was, therefore, not an absolute renal failure but a failure only in relation to the demand imposed.

An increased demand for work from the kidney is imposed by the parenteral injection of any protein to a degree that varies with its nature and with the conditions under which it is administered.

CARCINOMA OF THE CORPUS UTERI

End-Results of Treatment in 531 Cases from 1926-1940

HOWARD C. TAYLOR Jr., M.D. F.A.C.S., and WALTER F. BECKER, M.D.
New York, New York

CANCER of the uterus according to Bureau of Census statistics, caused the death in 1942 of 16 393 American women. Carcinoma of the endometrium is probably responsible for a fifth or more of these deaths since the ratio of corpus to cervical carcinoma has been variously estimated by different writers as 1 to 2.4 (10) 1 to 3.4 (19), 1 to 4.5 (18) and 1 to 8.2 (17). The importance of corpus carcinoma has been underestimated, partly because of its supposed infrequency, partly because of the persistent belief in its good prognosis.

Statistics on the results of the treatment of corpus carcinoma are partly responsible for the misconception about this disease. Methods of reporting cases of carcinoma of the corpus have never been standardized as they have, for instance, for cervical cancer. Too many reports have been based on cases selected for special treatment and the statistical principle of showing the results upon all cases applying to a given institute for treatment has not been followed. In the analysis of the cases to follow the attempt is to be made with the aid of data from several contributions in the literature to answer certain questions about cancer of the corpus.

The series to be reported includes all histologically proved cases of carcinoma of the cor-

pus uteri in patients admitted to the Memorial Hospital during the 15 year period from 1926 to 1940.¹ Only 7 patients are excluded, 5 who refused treatment and 2 who were referred back to the institution that had initiated treatment. Of the 531 patients considered, 368 had received no treatment prior to their admission to the Memorial Hospital and will be referred to as 'primary' cases. 163 had received previous treatment elsewhere and will be termed 'secondary' cases.

This report is concerned primarily with end results. Etiologic factors such as age incidence parity marital status and the menopause and symptomatology will be referred to only briefly. Pathology and therapy will be discussed in relation to end results.

ETIOLOGIC FACTORS

Age. The average age for the group of primary cases was 57.4 years, the standard deviation from the mean 8.8 years. The youngest patient was 30 years old and the oldest 79. The 5 year period of greatest incidence was 60 to 64 and 42 per cent of the patients fall in the decade between 55 and 64 years of age. The age distribution by 5 year periods is presented in Table I.

Marital status. Of the patients on whom data were available 88.5 per cent were mar-

¹These patients were treated under the immediate direction of Dr. William F. Healy who was in charge of the Gynecological Division during the years of this report.

From the Gynecological Division of the Memorial Hospital New York.

SURGERY GYNECOLOGY AND OBSTETRICS

130

TABLE I.—AGE DISTRIBUTION

Age group	Number	Per cent
30 - 34 years	4	1.1
35 - 39	11	2.9
40 - 44	14	3.8
45 - 49	41	11.0
50 - 54	68	18.2
55 - 59	72	19.3
60 - 64	85	22.8
65 - 69	56	15.0
70 and older	22	5.9
Total	373	100.0

ried or widowed 11.5 per cent had never married. The figure for the single women does not differ greatly from that of a United States Census report which stated that in 1940 in the New York Northeastern New Jersey Metropolitan area, 12.1 per cent of women over 35 were unmarried (22). A report by the British Clinical Cancer Research Committee (1) in 1941 which compared the ratios of married and widowed to single women among the patients suffering from cancer with that to be expected among living women at separate age groups, showed that the liability to carcinoma of the corpus is somewhat less among married and widowed than among single women. Pack and LeFevre noted that the percentage of single women with cancer of the body of the uterus was four times as great as the percentage of single women with carcinoma of the cervix.

Parity The parity was recorded in the histories of 461 patients. Of these, 31.5 per cent had never conceived and all the pregnancies had never ended in abortion that is, of 3.9 per cent had never had a full term pregnancy. In 1940 in the New York Northeastern New Jersey Metropolitan area, of women 35 years old and over who had ever married 16.7 per cent had never borne a child (22). The statistics in the Memorial Hospital series indicate, then, that women destined to develop corpus cancer marry with about the normal frequency but then exhibit a relatively high degree of infertility.

While the 1930 population, for which figures are not available, would be more suitable comparison year the proportions of single and childless women to 1940 are presumably at least as great as in 1930. Consistent differences between the corpus series and the comparative population will be underemphasized rather than overestimated. Mrs. Ruth F. Keith, biostatistician in the Statistics Department at Memorial Hospital, points out that the true differences between women with cancer of the body, biostatistician in the general population cannot be determined until groups of similar age, income level, education, age at marriage, occupation of spouse, etc., are compared. Death rates from cancer of the corpus of single, married, divorced and widowed women should also be compared.

TABLE II.—ONSET OF SYMPTOMS IN RELATION TO THE MENOPAUSE

	Number	Per cent
Menopause not yet reached	98	21.7
Menopause was artificially induced	23	4.7
Patient past the menopause	342	73.8
Average age of natural menopause—48.5 years		

Menopause The average age of the natural menopause was 48.5 years. As indicated in Table II 73.86 per cent of the patients were in the postmenopausal period, 21.17 per cent had not yet reached the menopause, and then had been an artificially induced menopause in 4.97 per cent of the cases. Data were lacking on 12.8 per cent of the patients.

Associated primary carcinomas Twenty-two of the patients had more than one primary carcinoma, making the incidence of double primaries 4 per cent. The frequency with which the other primary carcinomas occurred in particular sites was as follows: breast, 11; cervix, 3; vulva, 2; large bowel, 2; kidney, 1; esophagus, 1; bladder, 1; and lymphosarcoma, 1. Warren and Gates reported an incidence of 3.7 per cent in their series of 1,973 cancer autopsies. Hurt and Broders found that the frequency of multiple primary tumors among 2124 patients with malignant tumors treated at the Mayo Clinic in the calendar year 1929 was 3.34 per cent. Among the 2124 patients studied by Hurt and Broders, there were 71 cases of multiple malignant lesions. There were 8 cases of endometrial adenocarcinoma, and in every instance the associated lesion was in the breast or genitalia.

SYMPTOMATOLOGY

Vaginal bleeding was a symptom in 96.6 per cent of the cases, but was usually slight, characterized by the patient as "staining" or "spotting." In those women who had not yet reached the menopause, menorrhagia of many years' duration was not an uncommon complaint although more often the bleeding was of the intermenstrual type. The commonest picture of all was, of course, postmenopausal bleeding. An associated vaginal discharge was mentioned in the histories of 57 per cent of the cases. Twenty-two per cent of the patients were complaining of pain at the time of admission to the hospital.

TABLE III.—RELATION OF DURATION OF SYMPTOMS TO END-RESULTS

Duration of symptoms in months	Cases		Five year cures	
	Number	Per cent	Number	Per cent
Less than 6	125	35.92	48	38.4
6 11	82	23.56	33	40.2
12 23	65	18.68	27	41.6
24 35	33	9.48	13	39.4
36 47	16	4.59	8	50.0
48 59	7	2.01	2	28.6
60 or more	20	5.76	10	50.0
Total	348	100.00	141	40.5

The average duration of symptoms before treatment for the primary cases was 15 months. The histones tend to confirm the opinion that carcinoma of the corpus uteri is often slow in growth and may extend beyond the uterus only after many months or years. Yet there was evidently great variability in this respect. Several of the patients who had disease in an advanced stage had experienced symptoms for only a few days while many of those whose symptoms were of several years' duration were found to have a normal sized uterus with the cancer still confined to that organ.

It was surprising also that, at least in this series, there was no evidence that the failure of treatment was directly related to the length of the symptoms. The relative success in the group of cases of long duration suggests the possibility that in some of these at least the endometrial lesion was in the beginning a benign one. Several studies have presented evidence that hyperplasia of the endometrium may be a predisposing factor to the later development of cancer. The literature also contains reports of several instances of apparent transformation of hyperplasia into carcinoma, as indicated by a change in the character of the tissue obtained in successive curettings in the same patient.

THE END-RESULTS IN CARCINOMA OF THE CORPUS

The end results of the treatment of all patients with histologically verified carcinomas of the uterine fundus admitted to Memorial Hospital during the period 1926 to 1940 inclusive are summarized in Table IV.

At the Memorial Hospital all of the ward patients and a majority of the private patients are treated by members of the gynecologic division.

TABLE IV.—END-RESULTS FOR ALL CASES 1926-1940

	Memorial Hospital	Gynecologic Division
Total number of cases	531	483
Indeterminate group		
Dead as result of other causes and without recurrence	3	3
Lost track of without recurrence	5	15
Total number of indeterminate results	8	18
Determinate group		
Total number minus those of indeterminate group	474	437
Failures		
Dead as result of carcinoma or its treatment	245	230
Lost track of with cause (probably dead)		8
Living with recurrence	7	16
Total number of failures in treatment	7	54
Successful results		
Free of carcinoma after 5 years	20	183
Five year end-results		
Successful results divided by determinate group	(20/474) 4.2%	(183/437) 41.9%
Absolute cure rate		
Successful results divided by total number of cases	(20/531) 3.8%	(183/483) 37.7%

A total of 5 cases are 1. the Memorial Hospital during these years were excluded from consideration because, although probably carcinomas of the corpus, there was no histologic proof. Of the group, 2 refused treatment and was referred back to the institution back had begun treatment. Among the 24 primary cases treated without histologic proof there were no cures. Among the 30 secondary cases, there were 6 cases after 5 years.

vision. About a tenth of all cases, however are managed as private cases by attendants from other divisions. For completeness, it has seemed necessary to present figures for the entire hospital but, since only the cases of the gynecologic division could be supervised from a standpoint of technique, it was also necessary to report figures for this group separately. In most of the following tables, therefore, two groups of figures appear, those for the whole hospital and those for the gynecologic division. In general, however, there is a significant difference between results in the two groups. Of the 531 patients 483 were treated and private patients treated on the gynecologic division the remaining 48 were per- patients under the care of attending surgeons in other services.

Of the 531 patients 368 or 69 percent of the patients received all of the treatment.

TABLE V — END-RESULTS FOR PRIMARY CASES
1926 — 1940

	Memorial Hospital	Gynecologic Division
Total number of primary cases	368	336
Isteterminals group		
Dead as result of either causes and without recurrence	81	90
Lost track of without recurrence	13	30
Total number of isteterminals results	94	120
Determinals group		
Total number minus those of isteterminals group	274	216
Failures		
Dead as result of carcinoma or its treatment	163	59
Lost track of with cancer (probably dead)	5	3
Living with recurrence	9	8
Total number of failures in treatment	177	70
Successful results		
Free of carcinoma after 5 years or more	147	136
Five year end-results		
Successful results divided by determinals group	(147/274) 53.7%	(136/216) 62.9%
Absolute cure rate		
Successful results divided by total number of cases	(147/368) 39.9%	(136/336) 40.5%

here 163 or 39.7 per cent had undergone some treatment prior to their admission to the Memorial Hospital.

The absolute five year cure rate for the entire series including both primary and secondary cases, was 38 per cent. The 57 patients who died of other causes and without clinical evidence of recurrence and the patients who were lost track of without recurrence were considered failures in treatment.

END-RESULTS IN PRIMARY CARCINOMA OF THE UTERUS

In Table V, constructed according to a standard form in use for the reporting of end-results at the Memorial Hospital are shown the results in the 368 primary cases.

In this group there were 147 five year cures, giving an absolute cure rate of about 40 per cent (39.9). Since in this age group there is a considerable death rate from unrelated causes, a perhaps truer picture of the prognosis is given by accepting the figures for the determinate cases, after subtracting the cases lost

TABLE VI. — RELATION OF CLINICAL GROUP TO
END-RESULTS PRIMARY CASES ON GYNECOLOGIC DIVISION

Clinical group	Cases Number	Per cent	Five year cases Number	Per cent
Clinical Group I				
Uterus not enlarged	50	13.10	33	66.6
Clinical Group II A				
Uterus not larger than 2½ months' gestation	156	42.09	74	47.4
Clinical Group II B				
Uterus larger than 2½ months' gestation	90	8.76	11	12.4
Clinical Group III A				
Extension of carcinoma to cervix only	37	11.18	9	24.3
Clinical Group III B				
Extension of carcinoma beyond uterus	70	23.87	9	12.8
All Cases	331	100.00	136	41.2

*The records of 3 patients contained no data relative to clinical group.

track of without evidence of cancer and those dying of intercurrent illness. The effect of this correction is, however only to raise the apparent cure rate to about 45 per cent.

The relationship of clinical extent of disease to end results. A slight modification of Healy's (8) classification based on the palpable size of the uterus and the extent of disease at first examination was employed in dividing the primary cases into three clinical groups. This classification, which appears a highly practical one, is as follows:

Group I. Those cases in which there is no palpable evidence of uterine enlargement or extension of disease beyond the fundus.

Group II. Those cases showing uterine enlargement without fixation or other evidence of carcinoma elsewhere. This group was subdivided into Group II A in which were placed those patients in whom the uterus was larger than a 2½ months gestation and Group II B which included patients whose uterus was larger than a 2½ months gestation but still freely movable.

Group III. Patients exhibiting clinical signs of extension of cancer beyond the uterine fundus itself. Group III was further subdivided into those relatively favorable cases in which cancer had extended to the cervix only and into another group showing evidence of extension beyond the uterus into the vagina, parametria, and adnexa, and distant metastases.

The practical importance of this clinical classification is demonstrated in Table VI which

shows the relation of the clinical extent of disease to end results. Of the 50 patients in Group I, 66.6 per cent were alive and free of disease for 5 years or more. The absolute 5 year cure rate for the 136 patients with uterus enlarged up to the size of a 2½ months' gestation was 54.4 per cent. In 29 cases the uterine enlargement was greater than a 2½ months' gestation and only 37.9 per cent were 5 year cures. There were 37 patients in Group IIIA, 24.3 per cent of whom were living without evidence of recurrence at the end of 5 years. In Group IIIB were placed 79 patients with clinical evidence of extension of cancer beyond the uterus; the absolute cure rate in this group was only 11.2 per cent.

A similar plan of clinical division based on the size of the uterus was followed by Miller. His cases were divided into 3 clinical groups with the uterus normal in size in the first group, enlarged to the size of a 2½ months' pregnancy in the second, and to a 3 months' pregnancy in the third. The percentages of survival in these groups were 66.56 and 23 respectively while, had we used the same classification, our corresponding figures would have been 66.54, and 26.

The importance of the clinical extent of the disease is shown again in Graph 1 where the percentage of surviving patients is plotted at each 6 month interval after treatment was initiated. The survival curves show that the unfavorable prognosis of the more advanced cases is due especially to immediate deaths within the first 6 to 12 months after treatment. When a patient has survived the first 12 months without recurrence, her chance of survival is quite good regardless of her original condition. The survival curve is presented in the belief that it may be of aid in explaining the chances of cure to the anxious and often confused members of the families of patients with cancer of the corpus.

The relationship of histologic type to end results. In accordance with a plan previously employed in reporting carcinoma of the corpus from this hospital (Healy and Brown, 8) the 368 cases were divided on a histologic basis into 4 groups (Table VII).

Group A—adenocarcinoma, grades I and II. This group included also cases originally diag-

Graph 1. Relation of clinical extent of disease to end results in primary cases of carcinoma of corpus uteri.

nosed as 'adenoma malignum,' a term now regarded as undesirable. Of the 199 cases with these relatively differentiated tumors the absolute 5 year cure rate was 47.2 per cent. When only cases of 'adenoma malignum' are considered the figure becomes approximately 51 per cent.

Group B—adenocarcinoma, grades III and IV and embryonal carcinoma. Of these undifferentiated tumors there were 117 cases with a 5 year absolute cure rate of 22.8 per cent, a figure less than half of the preceding group.

Group C—adenocanthoma. The results in this interesting histologic variety showed a cure rate of 51.3 per cent among the 37 cases suggesting that squamous metaplasia tends to occur in relatively differentiated growths.

Group D—miscellaneous. In this group were placed 15 cases in which inadequate microscopic preparation made classification on this basis impossible.

It appears evident that the prognosis in endometrial cancer is strongly affected by the degree of differentiation of the tumor. This is in accord with a number of previous reports (Healy and Brown, 8; Taylor, etc.).

The unfavorable prognosis of the less differentiated tumors may depend on one or both of two possibilities. First, the grades III and

TABLE VII.—RELATION OF HISTOLOGIC TYPE TO END-RESULTS

Histologic type	Number of cases	Per cent of total	Five year cures	Number	Per cent
Adenocarcinoma, grades I and II	100	54.03	91	47	2

Adenocanthoma	37	10.03	9	51	3
Miscellaneous	5	4.03	5	33	3
Total	368	100.00	47	39	9

IV may be more fatal on account of a greater tendency to metastasize even when the original tumors are grossly of equal size. Second a greater rapidity of initial growth may have produced at the time of treatment a larger primary tumor and so affect prognosis simply on the basis of a more extensive local disease.

Table VIII shows that the second possibility is at least one of the factors. In clinical Group I only 14 per cent of the cases are of the undifferentiated types whereas in the more extensive lesions these histologic types are several times as frequent.

The relationship of the type of treatment to end-results. The determination of the best method of treating carcinoma of the corpus has evaded statistical analysis. Nor has it been possible on the basis of this series to offer any final answer as to whether surgery alone or in some combination with radium or x ray is most effective.

In all series, certainly in our own cases are selected for a special form of therapy on the basis of factors which themselves affect the end results. Of the most importance is the tendency to assign the patient who is a bad surgical risk, on account of obesity age or organic disease to a program of radiation therapy. Such patients give less than the average

results among radiated just as they would among surgically treated cases.

Some favorable selection for surgery is seen in the tendency to omit radiation in the very early or unsuspected cases of endometrial cancer in order to prevent the patient a discovery of the diagnosis. Some cases having a bad outlook are however added to the surgical group in the belief that the very bulky uterus is too large for any significant effect from intracavitary radium.

In general the individualization of treatment in cases of corpus cancer appears to favor the statistics for hysterectomy alone or in combination with radiation as opposed to a program depending exclusively on radiation therapy.

In reporting the effect of treatment on the Memorial series, the question of surgery radium and x ray will be considered first upon the entire series then with relation to the clinical extent of the disease and finally to the histologic type of tumor.

A few points may be noted about the techniques employed with the various therapeutic measures.

1. Radium. The standard method of treatment has been the intrauterine application of a straight applicator containing radium, individually constructed for each case so as to extend from the external os to the top of the uterine cavity. The usual initial dose has been 3600 millicurie hours. Patients to have surgery are admitted for hysterectomy 6 weeks after the radium treatment. Patients in whom surgery is contraindicated and for whom it is hoped radiation will suffice are now recurred after a 4 month interval and further radium inserted or the risk of a hysterectomy is then accepted if cancer is still present. In the earlier part of the period reported, however patients treated by radiation alone were simply observed unless bleeding recurred.

2. X-ray. Roentgen therapy was at first given with massive doses of 750 r each to 4 or 6 portals (14 by 21 cm.) using a 200 kilovolt machine at 70 centimeters with 0.5 millimeter copper filtration. More recently 250 kilovolt roentgen rays have been used, still with 4 to 6 pelvic ports, but with a divided dose each field receiving 8 treatments of 250 r each. Roentgen therapy is now given rou-

tinely after the radium in patients treated by radiation only and less regularly after hysterectomy, but in the years of the series being reported x ray when given was almost with out exception the initial therapeutic procedure.

3 Surgery The surgical operation employed has almost without exception been a total abdominal hysterectomy with removal of both adnexa. The cervix has been removed with only a small cuff of vagina and no attempt has been made to dissect out the lymph nodes or parametria.

In Table IX are presented the 5 year end results according to the method of treatment without regard to stage of the disease or histologic type. The figures are at first glance entirely in favor of the surgically treated cases. This is best shown by the figures in the summary indicating that of all cases in which a hysterectomy was performed 51.1 per cent survived 5 years without recurrence whereas among the cases with treatment limited to radium with or without x ray only 36.8 were alive and well after 5 years.

Perhaps the best evidence for the need of a hysterectomy is the frequency with which residual viable cancer is found in excised uteri following large doses of preoperative irradiation. Of the 119 patients of this series who were subjected to hysterectomy after having received as a rule 3600 millicurie hours of intrauterine radium 59 or 49.6 per cent, had microscopic evidence of viable cancer in the excised uterus. The absolute 5 year cure rate in the cases without residual carcinoma in the irradiated excised uterus was 73.8 per cent while only 44.1 per cent of the patients whose uterus harbored residual cancer survived 5 years.

Among 70 of the patients recently reported by Corscaden, treated by hysterectomy after intrauterine application of radium residual carcinoma was found in 50 per cent of the uteri. The possibility remains that an applicator more perfectly adapted to the varying sizes and shapes of the uterine cavity might result in a destruction of the carcinoma in a higher percentage of the cases treated.

Treatment in relation to the clinical stage
Further analysis of the series by dividing into stages according to the gross extension of the

TABLE IX —RELATION OF TREATMENT TO
END RESULTS

disease the cases in which patients were treated by each method shows that a more difficult group was assigned to radiation than to surgery (Table X).

From Table XI a condensation of Table X, it is evident that in the radium group there was twice the proportion of very advanced cases a difference in selection which might easily account for the difference in total end-results.

The better comparison is perhaps made by studying the results only in the clinical groups I IIA, and IIB which may be regarded as technically operable. There were 109 such operable patients treated by irradiation alone with an absolute 5 year cure rate of 52.3 per cent. A combination of irradiation and hysterectomy was used in the treatment of 90 similar cases with a cure rate of 56.6 per cent. Sixteen patients were treated by hysterectomy alone of whom 10 or 60.3 per cent, survived for 5 years. These differences are probably not statistically significant and it becomes difficult to explain why when surgical specimens so frequently show persistent cancer after radium, that the difference in cure rates among operable cases is not greater.

A greater contrast between surgically treated and radiated patients was recently reported by Corscaden in a report based upon 27 cases in which patients were technically operable and were treated by the intrauterine application of radium, and 25 similar cases in which patients were treated by a combination of irradiation and hysterectomy. The 5 year survival rates in the 2 groups of cases were 48 per cent and

^aThree group III B cases were too far advanced for treatment but were included

72 per cent respectively. Arneson collected from the literature a series of 473 cases in which patients were operable and were treated by radiation alone, and found that 53 per cent survived for 5 years.

Another important subject is the possible advantage of combining radiation with surgery in cases of carcinoma of the corpus in the hope of improving the results obtained by hysterectomy alone. Only 17 patients in this series were treated by surgery without radiation and these afford an insufficient control. The results on these few cases were, however, as good as in any group in which radiation was given in addition to surgery.

Review of several reports in the literature (Table XII) also fails to demonstrate a consistent effect on statistics when radiation is added to surgical treatment. Altogether it seems unproved that the cure rate in corpus cancer is being improved by preoperative or postoperative x ray or radium.

Treatment in relation to histologic type. The bearing of histologic type upon method of

treatment has been studied and the analysis of the series for this aspect is shown in Table XIII. A point of possible significance is the decided advantage evident when surgery is employed for the differentiated forms of cancer. For the adenocarcinoma of grades III and IV, however, the results for radiation alone appear to be as good as for surgery. It is possible that the radiosensitivity of these types is the determining factor and that metastasis has occurred so frequently by the time treatment is instituted that the removal of the uterus is a relatively unimportant step. The evidence for this special point is, however, still too fragmentary to base treatment upon it as a principle.

END-RESULTS IN PREVIOUSLY TREATED PATIENTS

The problem of the treatment of recurrent carcinoma of the corpus requires in itself a major study and it is accordingly intended to report the secondary cases in only enough detail to make this a complete statistical study of the work of the hospital on carcinoma of the endometrium.

One hundred and sixty three patients who had received prior treatment for corpus carcinoma were admitted to the Memorial Hospital during the 15 years under consideration (see Table XIV). Thirty of these women presented no clinical evidence of carcinoma on

admission, and the diagnosis was confirmed only by the microscopic examination of the material submitted from the institution at which treatment had been initiated. These were classed as "prophylactic" cases. The remaining 133 patients were termed recurrent cases since it was possible to make a diagnosis on biopsied or curetted tissue obtained after their admission to this hospital. No attempt was made to differentiate between persistent and recurrent disease.

The standard table for reporting end results is given for completeness for all secondary cases (Table XIV). Nevertheless, the 2 groups have a decidedly different significance and require separate comment (Table XV).

a The prophylactic group Twenty of the 30 patients in the prophylactic group were alive and free of disease after 5 years—an absolute cure rate of 66.6 per cent. This is the figure which may be anticipated in any series of operable cases which are treated by hysterectomy.

b The total recurrent group This group of patients treated for the first time in other institutions and referred to the Memorial Hospital with cancer still present is a miscellaneous one. It includes the inoperable patients with fixed uteri and large abdominal masses, recur-

rences in the vaginal vault and about the hymenal ring and urethra, and finally cancer redeveloping in cervical stumps. There were 33 five year cures among the 133 recurrent cases—an absolute cure rate of 24.8 per cent. This figure indicates that even when the first effort at cure is a failure, some hope still exists for control of the disease.

One point in regard to the recurrent group is worth noting. Among the 90 patients who

had been surgically treated before being referred to Memorial Hospital, 57 or 66.4 per cent, had received only a supracervical hysterectomy. Thirty five, or 61.4 per cent, of those women who had had a supracervical amputation of the uterus had histologically verified carcinoma in the cervical stump at the time of their initial examination here. It is obvious that entirely too many women who are suffering from vaginal bleeding are still being treated by a subtotal hysterectomy with out curettage or adequate examination of the cervix.

SUMMARY AND CONCLUSIONS

Five hundred and thirty-one histologically verified cases of carcinoma of the corpus uteri were admitted to Memorial Hospital during the period 1926 to 1940, inclusive. The absolute 5 year cure rate on this unsorted group of cases was 38 per cent.

The primary cases of the series numbered 386 of which 39.9 per cent were alive and well at the end of 5 years. By subtracting the patients lost track of when free of cancer and those dying of intercurrent, unrelated illness, the apparent cure rate for 5 years is about 45 per cent.

Of the secondary cases, there were 30 patients who came to the Memorial Hospital without clinical evidence of cancer and of these there were 20 five year cures. The patients admitted to the service with recurrences numbered 133 and, of these 24.8 per cent were alive and well after 5 years.

The prognosis in carcinoma of the corpus depends on 3 factors (a) the gross extent of the disease (b) the histologic type and (c) the type of therapy employed. Analysis of the present series was made to evaluate these points.

The effect of the gross extent of the disease is shown by the 5 year end results in 5 specified groups as follows. Group I uterus not enlarged, 66.6 per cent. Group II A, uterus not larger than a 2½ months gestation, 54.4 per cent. Group II B uterus larger than a 2½ months gestation, 37.9 per cent. Group III A, extension of carcinoma to cervix, 24.3 per cent. Group III B extension of carcinoma beyond uterus, 11.2 per cent.

The effect of histologic type is shown by the 5 year end-results in 3 classifications as follows adenocarcinoma, grades I and II 47.3 per cent adenocarcinoma, grades III and IV 22.8 per cent adenosarcoma, 51.3 per cent.

The relation of type of treatment to end-results is more difficult to evaluate. In the cases in which hysterectomy was performed a 5 year cure rate of 51.1 per cent was shown, while in the group of patients treated only by radiation the figure was 36.8 per cent. The group with treatment limited only to radiation contained, however more patients in a relatively advanced stage of the disease.

The question of whether the cure rate from hysterectomy is increased when radiation is given in addition could not be answered on the basis of the analysis of this material

THE EXCRETION AND CONCENTRATION OF PENICILLIN AND STREPTOMYCIN IN THE ABNORMAL HUMAN BILIARY TRACT II HEPATIC BILE

JERRY ZASLOW M.D., VIRGIL S COUNSELLER, M.D. F.A.C.S., and
FORDYCE R. HEILMAN M.D. Rochester Minnesota

IN a previous paper the results of studies of the excretion and concentration of penicillin and streptomycin in the human gall bladder were reported (6). We now wish to present our findings relative to the excretion and concentration of these antibiotic agents in the hepatic bile of the abnormal human biliary tract. The reader is referred to the previous paper for introductory remarks and for a review of the literature.

METHOD OF STUDY

Twenty three patients, each of whom had undergone exploratory choledochostomy and insertion of a T tube in the common duct, were selected. Sixteen of these were used to study the excretion of penicillin 15 to study the excretion of streptomycin. Eight patients were tested only for excretion of penicillin 7 only for excretion of streptomycin and 8 for both. Therefore, on 8 occasions the results with penicillin could be compared with those for streptomycin.

Within a 3 day period after operation each patient was given a single intramuscular injection of either 15 000 units of penicillin or 100 000 units of streptomycin. When both substances were studied in the same subject, a single injection of each was given separately on the same day. Usually 6 to 8 hours were allowed to elapse before study of the second antibiotic agent was undertaken. Specimens of bile were collected from the T tubes at intervals of one-half hour to 1 hour up to 3 hours after injection of the antibiotic agent. Specimens of blood were obtained at the same time

from 4 patients who were given penicillin, and from a similar number given streptomycin. The antibiotic activity of all specimens was determined in the same manner as was done in the previous study (6). Within a 3 week period the study was repeated for penicillin in 5 cases and for streptomycin in 8 cases, in order to determine any change that might have occurred in the ability of the liver to excrete the antibiotic agent.

When the patient was jaundiced at the time of operation it was noticed whether the jaundice was increasing, stationary or subsiding as shown by estimations of the serum bilirubin level. In addition in most cases either an oral hippuric acid test or a sulfobromophthalein hepatic function test was done during the stay in the hospital. The former was performed in the presence of an elevated serum bilirubin level the latter in its absence. These observations were made in an attempt to correlate hepatic function tests with the ability of the liver to excrete antibiotic agents. An excretion in the urine of 3 grams of benzoic acid or its equivalent in hippuric acid is a normal value for the hippuric acid test, and retention of dye, "grade 0" in the blood serum is a normal value for the sulfobromophthalein test.

RESULTS

I Penicillin The results are collected in Tables I and II and are represented in Figures 1 to 3 inclusive. Table I states briefly a few pertinent facts in the history and the essential laboratory studies of the individual patients. Table II indicates the levels of penicillin activity in the bile in the initial study done within the first 3 days after operation. Reference to Figure 1 shows the similarity of the blood levels of the 4 patients studied. It is very likely that, had the other patients been so

From the Division of Surgery, Mayo Foundation and the Divisions of Surgery and Bacteriology, Mayo Clinic.

Abridgement of portion of thesis submitted by Dr. Zaslow to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of M.S. in Surgery.

Fig. 1. Levels of penicillin activity in blood serum and hepatic bile after 15,000 units of penicillin had been given intramuscularly. Four patients were used for the blood curves and 16 for the bile curves. Of the latter 5 failed to excrete penicillin into the bile. The graph demonstrates the similarity of the curves of the levels in blood and dissimilarity of those in bile.

studied, similar curves would have been obtained. On the other hand a composite graph of the levels in the bile shows great variation in the height and shape of the curves. It is the purpose of this study to determine the factors responsible for this variation. In addition it is noticed that the levels of activity are higher in the bile than in the blood, indicating that the liver concentrates penicillin.

The patients were divided into three groups, on the basis of their ability to excrete the penicillin on initial study: those who failed to excrete penicillin, those who excreted it in very small amounts, and those who excreted it in high concentration. An arbitrary figure of 0.24 unit per cubic centimeter was decided on to separate those who excrete small from those who excrete large amounts, because in a previous study (6) it was observed that the smallest concentration of penicillin in gall bladder bile obtained within the first 4 hours after injection was at least 0.24 unit per cubic centimeter. Since all persons but one in that investigation had presumably normal hepatic function, it was assumed that that level was representative of the lowest limit of excretion in a normal subject.

It is realized that the volume of bile excreted during the 3 hour period for each study is not the same for all patients. However the amounts excreted during 24 hours were usually quite similar: 250 to 350 cubic centimeters. While it is conceivable that if one patient excretes 50 cubic centimeters over the 3 hour period of study, whereas another excretes 20 cubic centimeters, the first patient may dilute any antibiotic agent excreted and mask the results, this was not usually the case. Often the highest levels of penicillin were found among patients excreting relatively large volumes of bile at the time of study, and the lowest levels among those excreting small amounts of concentrated bile. Generally speaking, however, this factor was of little importance, since most patients excreted similar volumes of bile.

Group 1: no excretion of penicillin. Five patients failed to excrete penicillin within the 3 hour period of observation (Table I). In several cases the observations were repeated the following day with similar results. A short résumé of the history and laboratory findings in these cases follows.

CASE 1. The patient gave a history of recurrent colic in the upper part of the abdomen, often with

CASE 3 The patient had undergone cholecystectomy previously. For 1 month he had continuous jaundice and acholic stools, but no chills, fever or pain. Exploratory choledochostomy was performed. No obstruction was found, and it was the surgeon's impression that the patient had intrahepatic jaundice. The preoperative serum bilirubin levels varied from 20.1 milligrams per 100 cubic centimeters to 35.5 milligrams per 100 cubic centimeters direct and from 1.8 milligrams per 100 cubic centimeters to 3.8 milligrams per 100 cubic centimeters indirect. A preoperative hippuric acid excretion test showed severe impairment of hepatic function since only 5.63 grams of hippuric acid (or 1.79 gm. of benzoic acid) was excreted in the urine. On the fourth postoperative day there was no excretion of penicillin in specimens of bile collected over hourly periods. Postoperatively, the serum bilirubin levels remained high, and the patient was dismissed from the clinic with his T tube in place.

CASE 4 The patient had had recurrent colic in the right upper quadrant of the abdomen for 1 year and had been icteric for 3 weeks. The serum bilirubin level was 4 milligrams per 100 cubic centimeters direct and 1 milligram per 100 cubic centimeters indirect. Following an oral hippuric acid test of hepatic function, it was reported that only 2.04 grams of benzoic acid had been excreted in the urine (normal, 3 gm.). Two cultures of bile from the common duct were reported as positive for *Escherichia coli*. No

penicillin was excreted in the bile on the fourth postoperative day. The patient's jaundice cleared rapidly and he had no immediate postoperative difficulty.

CASE 5 The patient was admitted with a history of intense jaundice for several months. The serum bilirubin level was 60.6 milligrams per 100 cubic centimeters direct and 4.2 milligrams per 100 cubic centimeters indirect. The oral hippuric acid test of hepatic function was reported as giving normal results. At operation a carcinoma of the gall bladder with a local metastatic growth obstructing the common duct was found. The duct was opened, "white" bile was obtained, and a T tube was inserted. On the fifth postoperative day there was no excretion of penicillin into the bile. The patient was dismissed unimproved on the eleventh postoperative day.

It is interesting to observe that in 4 of the 5 cases there was persistent jaundice before operation and in 2 of these cases "white bile" was obtained from the bile ducts at operation. However, even when color returned to the bile in 1 of the cases, indicating that some of the function of the liver was returning, penicillin was still not excreted in the bile. In 4 of the 5 cases there was impairment of hepatic function as shown by the usual tests of hepatic function. In 1 case, in which the patient was not icteric preoperatively, jaundice, chills, and fever developed soon after operation. During this time no penicillin was excreted, but as the cholangitis cleared, parenterally given penicillin was recovered in the bile.

Group 2 excretion of small amounts of penicillin

CASE 6 The patient had had intermittent chills and fever for 3 months and intermittent jaundice for 10 months. The serum bilirubin level on admission was 10.6 milligrams per 100 cubic centimeters direct, and 2.1 milligrams per 100 cubic centimeters indirect. Operation was performed 10 days later when the jaundice was definitely subsiding. Cholecystectomy and choledocholithotomy were performed and a T tube was left in place. On the third postoperative day penicillin that had been administered parenterally was excreted in a concentration of 0.03 unit per cubic centimeter of bile in the 1 hour specimen, but all the other specimens up to 3 hours showed no activity.

CASE 7 The patient had had a biliary fistula since cholecystectomy had been performed 4 months before. The serum bilirubin level varied from 2.6 milligrams per 100 cubic centimeters to 3.5 milligrams per 100 cubic centimeters direct. A stone was removed from the common duct and a T tube was inserted. On the second postoperative day all specimens of bile collected up to 3 hours showed a maximal penicillin level of 0.19 unit per cubic centimeter after parenteral administration of penicillin.

§Level of serum bilirubin falling when study was made

¶Normal serum bilirubin when study was made

In both of these cases there was a history of chronic icterus and recurrent episodes of cholangitis. Both patients were apparently recovering from acute obstructive episodes when the study was made.

Group 3 excretion of large amounts of penicillin. The remaining 9 patients excreted penicillin in a concentration of at least 0.25 unit per cubic centimeter of bile. Five of these had no previous history of jaundice and in 4 of the 5 cases the maximal concentration of penicillin in bile varied from 0.5 unit per cubic centimeter to 2 units per cubic centimeter (Cases 13 to 16 inclusive). In the one nonicteric case (Case 12) in which the level did not exceed 0.25 unit per cubic centimeter it was persistent at this concentration in all except the half hour specimen. The remaining 4 patients (Cases 8 to 11 inclusive) gave a history of rather recent onset of jaundice and at the time of study they gave evidence of subsiding icterus. Two of these showed impairment of excretion of hippuric acid.

In general the highest levels of excretion of penicillin were found among those patients who had no history of recent or past jaundice and who exhibited good hepatic function as shown by the tests employed. With a history of persistent jaundice and with impairment of hepatic function less penicillin was excreted until in 5 cases none was excreted in the bile.

Excretion studies were repeated a week after the initial tests in 5 cases (Table I). Two of these have been described in detail in the previous paragraphs (Cases 1 and 7). It was seen in Case 1 that after 12 days of T tube drainage penicillin was excreted in a concentration of 0.12 unit per cubic centimeter where initially there was no excretion. After 7 weeks the patient in Case 7 was still unable to excrete penicillin. The 3 other patients followed showed a definite increase in ability of the liver to excrete penicillin (Cases 7, 8 and 9) as indicated in Figures 2 and 3. One of these patients (Case 7) who had an excretion level of 0.1 unit per cubic centimeter initially

showed an increase to 1 unit per cubic centimeter in the half hour specimen. The patient in Case 8 excreted 0.25 unit per cubic centimeter soon after operation and 0.5 unit per cubic centimeter 5 days later. This was a patient who had recurrent jaundice of 1 month's duration and good hepatic function as shown by the oral hippuric acid excretion test. The patient in Case 9 excreted 0.25 unit per cubic centimeter at first, and 0.5 unit per cubic centimeter later.

Consequently it is noted that in 4 of the 5 patients followed there was a definite increase in the ability of the liver to excrete penicillin after a variable period of T tube drainage. Also from this it would appear that the lower limit of excretion 0.25 unit per cubic centimeter is an index of impaired excretion since in all 3 cases in which hepatic function was not seriously impaired a level of at least 0.5 unit per cubic centimeter was obtained on the second determination after a week of drainage. While this group is small the results are suggestive. In addition these results support a previous finding that the patients without jaundice or hepatic damage excreted at least

0.5 unit per cubic centimeter on the first determination soon after operation (Cases 13 to 16 inclusive) as well as the finding that in 2 cases in which the cystic duct was patent the level after 45 minutes was at least 0.5 unit per cubic centimeter in spite of possible dilution in the gall bladder (6).

2 Streptomycin The results are collected in Tables III and IV and are represented in Figures 4 to 7 inclusive. Table III states briefly a few facts in the history and essential laboratory findings. Table IV indicates the levels of streptomycin activity in the bile on initial study done soon after operation. Reference to Figure 4 demonstrates the constancy of the height and persistence of the curves of streptomycin activity in the blood serum of each of the 4 patients so studied. A similar curve might be expected in all the other subjects were blood serum levels determined for them. As was true with penicillin however the streptomycin levels in hepatic bile varied in most of these cases. In addition the levels of activity in the bile were generally less than in the blood suggesting that the liver did not concentrate streptomycin.

Here too it is well to divide the patients into 3 groups according to their ability to excrete streptomycin in the bile on initial study soon after operation. An arbitrary figure of 1 unit per cubic centimeter of bile was chosen to separate those who excreted small from those who excreted large amounts. This figure corresponds to 0.24 unit per cubic centimeter of bile chosen for penicillin, and was arrived at in the same manner (see the section on penicillin).

Group 1 no excretion of streptomycin. Three patients failed to excrete streptomycin in the bile during the 3 hour period observed. One of these has been described previously in detail in the section on excretion of penicillin (Case 2). A brief history of the other 2 patients follows.

CASE 17 The patient had a history of dark urine, light stools, and jaundice for 3 months. A serum bilirubin level a week before operation was 1.55 mg. per 100 cubic centimeters direct and 2.5 mg. per 100 cubic centimeters indirect. The hippuric acid test of hepatic function showed definite impairment. At operation cholecystectomy and choledocholithotomy were performed, and a T tube

Fig. 4. Levels of streptomycin activity in blood serum and hepatic bile after 100,000 units of streptomycin had been given intramuscularly. Four patients were used for the blood curves and 15 for the bile curves. Of the latter 3 failed to excrete streptomycin in the bile. The graph demonstrates the similarity of the curves of the levels in blood and dissimilarity of those in bile.

was inserted. Two days after operation no streptomycin was excreted in the bile. This patient was not studied further.

CASE 18. A biliary fistula developed following cholecystectomy done 3 months before the patient came to the clinic. On several occasions when the fistula became obstructed she had chills, fever, and jaundice. On admission her serum bilirubin level was 8.9 milligrams per 100 cubic centimeters direct and 0.9 milligram per 100 cubic centimeters indirect. Several days later the common duct was reconstructed over a T tube. Studies of excretion of streptomycin on the third postoperative day showed no excretion in the bile, in spite of the fact that the serum bilirubin level was almost normal and the hippuric acid test of hepatic function gave definitely normal results. All studies were repeated 3 weeks later with the same results.

Group 2. excretion of small amounts of streptomycin. Two patients excreted a maximal concentration of less than 1 unit per cubic centimeter of bile.

CASE 19. Operation was performed because of chronic dyspepsia with recurrent bouts of colic in the right upper quadrant of the abdomen for several years. A functioning gall bladder with stones was found on roentgenographic examination. At opera-

tion greatly dilated common and cystic ducts were found and the liver was reported as showing 'hepatitis, grade 1+'. Cholecystectomy and choledochostomy were performed. The following day a streptomycin excretion study was made. The maximal level attained was 0.7 unit per cubic centimeter in the 1½ hour specimen. A serum bilirubin level the following day was 9.1 milligrams per 100 cubic centimeters direct and 1.6 milligrams per 100 cubic centimeters indirect. A hippuric acid test of hepatic function done 5 days later showed severe impairment. It was impossible to repeat the streptomycin excretion study since little material was obtainable from the T tube after the fourth day. However on the ninth postoperative day the serum bilirubin level was 3.6 milligrams per 100 cubic centimeters direct and 0.8 milligram per 100 cubic centimeters indirect.

CASE 20. Cholecystectomy and choledochostomy had been performed in 1943. The patient was well until 2 weeks before his present admission when pain in the right upper quadrant of the abdomen, fever, dark urine, and jaundice developed. The serum bilirubin level 4 days before operation was 5.1 milligrams per 100 cubic centimeters direct and 3.4 milligrams per 100 cubic centimeters indirect. The hippuric acid liver function test gave normal results. Choledocholithotomy and choledochostomy were performed. On the second postoperative day the pa-

Fig. 5.

Fig. 6.

Figs. 5, 6, and 7. Effect of relief of biliary obstruction on streptomycin excretion in hepatic bile. Definite increase of excretion to 3 weeks after operation over that 3 days after operation.

tient failed to excrete more than 0.6 unit of streptomycin per cubic centimeter of bile. However, when the study was repeated 3 weeks later, at which time his serum bilirubin level was 2.4 milligrams per 100 cubic centimeters direct and 0.9 milligram per 100 cubic centimeters indirect, the streptomycin activity of the 12½ hour specimen of bile was 1.12 units per cubic centimeter.

In résumé, one patient (Case 2) failed to excrete either streptomycin or penicillin in separate studies. This fact suggests that the excretion of these antibiotic agents is subject to the same factor of adequate hepatic func-

tion. As with penicillin 2 of the 3 patients who failed to excrete streptomycin in the bile had a history of persistent jaundice before operation and both showed impairment of response in the hippuric acid excretion test. The results found in the third patient (Case 18) are somewhat difficult to explain. Although her hippuric acid excretion test and sulfobromophthalen hepatic function test gave normal results, she failed to excrete streptomycin on 2 occasions, 3 weeks apart. The results of the first study done soon after operation might be ex-

Fig 7

plained on the basis of a recent episode of obstructive jaundice which had temporarily impaired some of the hepatic functions (such as streptomycin excretion). However after 3 weeks when her jaundice had completely subsided it was expected that she would excrete streptomycin. It would appear that the excretion of streptomycin is a hepatic function quite apart from all the others since it is well known that many hepatic functions may be normal while others are definitely impaired.

Of the 2 patients who excreted small amounts of streptomycin in the bile one had definite hepatitis, as shown by the surgeon's operative note corroborated by a definitely impaired hippuric acid excretion test. The other patient was studied soon after the onset of an episode of obstructive jaundice due to a stone in the common duct. The serum bilirubin was elevated at this time. However in a repetition of the study 3 weeks later when jaundice had subsided, he excreted a concentration of streptomycin twice that found on primary investigation. This was in the presence of good hepatic function as shown by the hippuric acid excretion test.

Group 3: excretion of large amounts of streptomycin. Ten patients excreted more than 1 unit per cubic centimeter on initial study. In 2 cases the serum bilirubin levels were normal at the time of examination. In

the other 8 cases the jaundice was definitely subsiding. The level of streptomycin activity in all of these cases varied from 1.05 units cubic centimeter to 3.8 units per cubic centimeter.

As with penicillin the highest levels streptomycin activity were among those patients who had no history of jaundice and had normal hepatic function. With persistent jaundice and impairment of hepatic function streptomycin was excreted in lesser amount until in 3 cases none was excreted.

In all cases but one where the hippuric acid excretion test gave normal results and no jaundice was present at the time of study the excretion level was more than 2 units cubic centimeter. However in the one exception a healthy robust man with no previous history of jaundice and with good hepatic function excreted only 1.5 units per cubic centimeter. This then must be considered normal level.

After a lapse of 1 to 3 weeks the studies were repeated for 8 patients (Table II). Two of these failed to excrete streptomycin even after a period of prolonged jaundice (Cases 2 and 18). They have both been described fully elsewhere. In all the other cases there was a definite increase of excretion that in several the level in the bile was doubled (Cases 7, 8, 9, 20, 22 and 23). After

period of T tube drainage, regardless of the primary condition the minimal excretion level in those tested was 1.8 units per cubic centimeter compared to 1.05 units per cubic centimeter on initial examination. It would appear then, that the lower limit of excretion chosen as normal namely 1 unit per cubic centimeter is an index of some impairment of ability to excrete streptomycin, since in all cases in which the studies were repeated later a higher level of excretion 1.8 units or more per cubic centimeter was found. In 3 weeks the patient in Case 20 doubled his ability to excrete streptomycin and although the level was only 1.12 units per cubic centimeter it is quite possible that, were the studies repeated again, the level would have been higher. Further repetition of the studies was not practicable in this case since the T tube was removed several days later.

In 8 cases studies were carried out with both penicillin and streptomycin (Cases 2, 7, 8, 9, 10, 12, 14, and 16). Reference to Tables I and III demonstrates how both substances are excreted quite similarly by the same patients. As mentioned previously 1 patient (Case 3) failed to excrete either penicillin or streptomycin. When a large amount of one was excreted a large amount of the other was usually also excreted. In 3 cases studies were repeated at a later date. In all cases there was an increase in the excretion of both antibiotic agents, and to a similar degree. This small series indicates the similarity of their excretion in hepatic bile.

COMMENT

In general the concentration of an antibiotic agent excreted in the hepatic bile is roughly inversely proportional to the degree of hepatic damage. In any case of obstructive jaundice as the obstruction persists more and more evidence of hepatic damage appears. The ability to excrete penicillin or streptomycin seems to be a rather sensitive index of hepatic damage. Early in the course of one case of cholangitis (Case 1) no penicillin was excreted but, as soon as the symptoms and signs of infection subsided penicillin was excreted into the bile. In all cases of long persistent obstructive jaundice no antibiotic

agent was excreted. In less prolonged obstruction there was some excretion. However in all cases but one in which excretion studies were repeated after one or more weeks of mechanical drainage with relief of obstruction penicillin was present in greater amounts than initially. The significance of this is obvious. It has long been recognized that the condition of patients who have cholangitis of greater or lesser degree improves with mechanical drainage. Hepatic function returns to normal, and very often the cholangitis is overcome. As is true with other regions of enclosed infection surgical drainage is necessary to institute resolution and repair.

As a result of this study it appears that a minimal level of 0.5 unit of penicillin activity per cubic centimeter of bile within a 3 hour period after an intramuscular injection of 15,000 units of penicillin is indicative of a relatively normal liver. The same is true for a level of 1.5 units of streptomycin per cubic centimeter of bile after an intramuscular injection of 100,000 units of streptomycin. Levels less than these suggest some impairment of hepatic function. The facts supporting this conclusion are first, that the few normal patients studied excreted at least those levels second that all patients who excreted less than these levels initially were able to excrete at least these levels 1 or more weeks later.

One patient had intrahepatic jaundice. He was unable to excrete penicillin. In view of our previous observations, this was not surprising. In intrahepatic jaundice, hepatic cellular damage and obstruction of the biliary canaliculi resulting from degenerative processes in the hepatic cells are present. This combination appears to prevent penicillin from entering the extrahepatic bile ducts.

The clinical application of these findings is worthy of consideration. In many cases cholangitis is treated conservatively. All the agents which might combat the infecting organisms are employed. Until recently the sulfonamides were administered with the hope that they might prove useful. No references to the excretion of these drugs into the bile in cases of cholangitis were found. The few reports of cases in the literature are rather contradictory

and are usually based on clinical observation (1-5) It is known that in many cases cholangitis goes into long periods of quiescence in the absence of any active treatment. The cures attributed to the sulfonamides under these circumstances are open to question particularly in view of the findings in the present study. While it cannot be said that the sulfonamides are excreted into the bile in the same manner as are the antibiotic agents, the few reports available suggest that they do behave similarly.

Generally speaking in the presence of definite cholangitis whenever possible it is considered good treatment to institute drainage. While at times this may be medical more often it is surgical. This is so because such cases are usually associated with obstruction in the biliary tract. It is the usual surgical experience that in these cases the response to such measures is good.

While obstruction to the biliary tract is still present the antibiotic agents do not appear to get into the bile. In addition the antibiotic agents, in greater or lesser amounts were excreted in the bile in all cases in which the jaundice was subsiding and as the serum bilirubin levels returned to normal the antibiotic levels in the bile increased.

Infection in the hepatic parenchyma itself presents still another problem. In normal dogs it has been shown that there is a high concentration of penicillin in the liver after parenteral administration of penicillin. Whether this is the case in the obstructed and infected liver is open to question. While an antibiotic agent will reach the hepatic cells through the blood stream its ability actually to enter or bathe the diseased cell is as yet unknown. That it will keep a localized infection in one part of the liver from spreading to other regions in the parenchyma is very likely. That it will keep an infection still localized in the extrahepatic bile ducts from spreading up to the hepatic cells is also possible. Unfortunately the clinician usually sees the patient who has cholangitis when the process has already invaded the liver itself. However in the absence of evidence to the contrary in cases of cholangitis administration of antibacterial agents would seem indicated in order to protect the liver it

self with the hope that the infection had not yet reached the intrahepatic canaliculi.

The problem of ridding the biliary tree of an infecting organism is not as hopeless as may appear from some of the foregoing remarks. Any patient who has a history of recurrent cholangitis should first be rid of the contributing factor if it is at all possible. This will include removal of stones, repair of strictures or an attempt to sidetrack the food stream in biliary intestinal anastomoses. When this is done it may be expected that the antibiotic agents will get into the biliary tree. If the responsible organism is known the appropriate antibacterial agent may be given. Within a reasonable period the infection should be overcome. While it may be possible to overcome the organism in a case of recurrent obstructive cholangitis during a period when the inflammation has subsided (for antibiotic agents often do get into the bile in effective concentration) the process is apt to repeat itself unless the etiologic mechanical factor is removed.

CONCLUSIONS

1. After the intramuscular injection of 15 000 units of penicillin or 100 000 units of streptomycin

a. The antibiotic agent is excreted in high concentration in the hepatic bile of normal patients.

b. A minimal level of 0.5 unit per cubic centimeter for penicillin activity or 1.5 unit per cubic centimeter for streptomycin activity in hepatic bile within 3 hours is indicative of normal liver. Lower levels suggest impairment of excretion.

c. The level of penicillin activity in the bile exceeds that in the blood within the first hours indicating that the liver concentrates this antibiotic agent.

d. The level of streptomycin activity in the bile is less than that in the blood within the first 3 hours indicating that the liver does not concentrate this antibiotic agent.

2. In the presence of obstructive jaundice the ability of the liver to excrete the antibiotic agent is impaired.

3. The greater the degree of hepatic damage the less is the amount of antibiotic agent present in the hepatic bile.

period of T tube drainage regardless of the primary condition the minimal excretion level in those tested was 1.8 units per cubic centimeter compared to 1.05 units per cubic centimeter on initial examination. It would appear then that the lower limit of excretion chosen as normal namely 1 unit per cubic centimeter is an index of some impairment of ability to excrete streptomycin since in all cases in which the studies were repeated later a higher level of excretion 1.8 units or more per cubic centimeter was found. In 3 weeks the patient in Case 20 doubled his ability to excrete streptomycin and although the level was only 1.12 units per cubic centimeter it is quite possible that, were the studies repeated again the level would have been higher. Further repetition of the studies was not practicable in this case, since the T tube was removed several days later.

In 8 cases studies were carried out with both penicillin and streptomycin (Cases 2, 7, 8, 9, 10, 12, 14, and 16). Reference to Tables I and III demonstrates how both substances are excreted quite similarly by the same patients. As mentioned previously 1 patient (Case 2) failed to excrete either penicillin or streptomycin. When a large amount of one was excreted a large amount of the other was usually also excreted. In 3 cases studies were repeated at a later date. In all cases there was an increase in the excretion of both antibiotic agents, and to a similar degree. This small series indicates the similarity of their excretion in hepatic bile.

COMMENT

In general, the concentration of an antibiotic agent excreted in the hepatic bile is roughly inversely proportional to the degree of hepatic damage. In any case of obstructive jaundice, as the obstruction persists, more and more evidence of hepatic damage appears. The ability to excrete penicillin or streptomycin seems to be a rather sensitive index of hepatic damage. Early in the course of one case of cholangitis (Case 1) no penicillin was excreted but, as soon as the symptoms and signs of infection subsided, penicillin was excreted into the bile. In all cases of long persistent obstructive jaundice no antibiotic

agent was excreted. In less prolonged obstruction there was some excretion. However in all cases but one in which excretion studies were repeated after one or more weeks of mechanical drainage with relief of obstruction, penicillin was present in greater amounts than initially. The significance of this is obvious. It has long been recognized that the condition of patients who have cholangitis of greater or lesser degree improves with mechanical drainage. Hepatic function returns to normal, and very often the cholangitis is overcome. As is true with other regions of enclosed infection, surgical drainage is necessary to institute resolution and repair.

As a result of this study it appears that a minimal level of 0.5 unit of penicillin activity per cubic centimeter of bile within a 3 hour period after an intramuscular injection of 15,000 units of penicillin is indicative of a relatively normal liver. The same is true for a level of 1.5 units of streptomycin per cubic centimeter of bile after an intramuscular injection of 100,000 units of streptomycin. Levels less than these suggest some impairment of hepatic function. The facts supporting this conclusion are first, that the few normal patients studied excreted at least these levels; second, that all patients who excreted less than these levels initially were able to excrete at least these levels 1 or more weeks later.

One patient had intrahepatic jaundice. He was unable to excrete penicillin. In view of our previous observations, this was not surprising. In intrahepatic jaundice, hepatic cellular damage and obstruction of the biliary canaliculi resulting from degenerative processes in the hepatic cells are present. This combination appears to prevent penicillin from entering the extrahepatic bile ducts.

The clinical application of these findings is worthy of consideration. In many cases cholangitis is treated conservatively. All the agents which might combat the infecting organisms are employed. Until recently the sulfonamides were administered with the hope that they might prove useful. No references to the excretion of these drugs into the bile in cases of cholangitis were found. The few reports of cases in the literature are rather contradictory

THE EFFECT OF RADIATION ON VAGINAL CELLS IN CERVICAL CARCINOMA

1 Description of Cellular Changes

RUTH M GRAHAM BS Boston Massachusetts

THE effect of roentgen rays on carcinoma of the cervix has long been of great interest to both radiologists and gynecologists. Since most cervical carcinomas are treated by irradiation any additional knowledge either concerning the radiosensitivity of cervical tumors or the ultimate prognosis would be of value. Any advance in the treatment of this disease by roentgen therapy will depend on further knowledge of the effect and the efficacy of the treatment as it is used at the present time.

The vaginal smear method presents a unique opportunity to study the effects of radiation on cervical malignancy. The vaginal smear is obtained with such ease by merely taking a sample of the vaginal secretion that a patient may be followed as often or as long as desired. The method has the further advantage that a representative group of all the cells both normal and malignant of the vaginal and cervical mucosa are seen not a limited portion as in serial biopsies. We have attempted to determine the effects of x ray and radium on cervical carcinoma by means of the vaginal smear. We are stating here only the effect of radiation on individual cells. The possible prognostic significance of the method will be discussed in a subsequent publication.

In 1921 Frankle and Amreich studied a series of cases of carcinoma of the cervix by means of biopsies during treatment with radiation. They describe marked swelling of the cells during x ray and radium treatment. Vacuolization of the malignant cells was also seen as a distinct part of the response to x ray treatment (2).

From the Vincent Memorial Laboratory of the Vincent Memorial Hospital (the Gynecological Service of the Massachusetts General Hospital).

This work was supported in part by a grant from the American Cancer Society (Massachusetts Division) Inc.

Dustin in 1927 studied 7 cases of epidermoid carcinoma in radiated patients by means of serial biopsies. He has divided the changes seen into four phases. The first phase is that of pyknosis of the nuclei and a decrease in the number of mitoses. The second phase is an increase in the number of atypical mitoses. The third phase represents such an increase in atypical mitoses that no normal mitotic figures were seen. The fourth phase he calls a rise in normal division of cells.

In 1930 Meigs and Parker (6) reported on 5 cases of epidermoid carcinoma on which daily biopsies were done during treatment. The number of both normal and abnormal mitoses was determined. They mention the increase of atypical mitoses on the fourth day after radium treatment and the eventual disappearance of atypical division.

Frola in 1933 reported 47 cases of cervical carcinoma studied by means of serial biopsies during treatment. Forty four cases were of epidermoid carcinoma and 3 of adenocarcinoma. He described the atypical mitoses as increasing and then disappearing. The complete disappearance of the malignant cell took place from the eleventh to the fortieth day of treatment. Pyknosis of the nuclei was a prominent feature of the reaction. Degeneration was variable. The sclerosis of blood vessels showed great variation. The connective tissue was infiltrated with polymorphonuclear leucocytes, lymphocytes and occasionally plasma cells. Almost half of the cases showed foreign body giant cell reaction at termination of treatment. He speaks of maturation evolutive in which the undifferentiated malignant cells mature to become large cells whose nuclei show a sharp nuclear border and are poor in chromatin. There is keratinization and hyalinization of the cells with formation of pearls. Frola also (1)

4 In the presence of long persistent obstructive jaundice no antibiotic agent is excreted in the bile.

5 As the level of serum bilirubin falls following relief of obstruction of the common duct, more and more of an antibiotic agent is excreted in the bile.

6 Penicillin and streptomycin will probably not be useful in treatment of acute or chronic obstructive cholangitis.

7 The etiologic mechanical factor should be removed in all cases of obstructive jaundice with cholangitis before streptomycin or peni-

cillin can be expected to overcome the infecting organism

staining deeply basophilic with large active nuclei. The outer layer basals are larger cells having a nucleus similar to that of the inner layer basal cell. Their size increase is due to an increase in cytoplasm rather than nucleus (Fig. 1) The basophilic cytoplasm of the outer layer basal is not so deeply staining and is more transparent. The basal cells are vacuolated occasionally but the vacuoles are usually quite small and quite evenly distributed or as in the case of the cervical basal cells there is one large vacuole with the nucleus pushed to one side—the signet ring type of cell (Fig. 2) It is important to emphasize that the nuclei of these vacuolated cells of the basal series appear normal in both size and appearance.

The next layer of the vaginal mucosa is composed of precornified cells. This layer is intermediate between the basal layer and the superficial vaginal epithelium. These cells have abundant lightly staining basophilic, transparent cytoplasm. The cytoplasmic nuclear ratio is greatly increased in comparison to that of the basal cells. The cytoplasm may be wrinkled or granulated and the cell borders are often irregular due to the folding over of the cytoplasm (Fig. 3) The nucleus is small and smoothly granular in appearance.

The cells of this type are very rarely if ever vacuolated.

The superficial layer of the vaginal mucosa is composed of cornified cells. These cells are similar to the precornified except for two distinct differences i.e. the nucleus is small and pyknotic and the cytoplasm is acidophilic (Fig. 3) The same statements concerning wrinkling, folding and granulation of the cytoplasm apply to these cells of the superficial layer.

Leucocytes are seen very often in the vaginal secretion. In positive smears they are a to be more numerous than in normal smear. The clumping of leucocytes in tight groups, even more frequently associated with the presence of malignant cells. The greatest majority of the leucocytes are polymorphonuclears but lymphocytes do appear.

Histiocytes are present in normal smear. Phagocytic histiocytes are not as common as the small histiocyte. These cells are smaller than the inner layer basal cell. Their nuclei are seldom perfectly round, usually bear either oval or crescent shape. They have finely vacuolated cytoplasm whose cell borders are often indistinct (Fig. 4) Foreign body giant cells are included in the group of histiocytes seen in the vaginal secretion. They

phasizes the metaplasia of the cells lining the cervical mucous glands during radiation.

In 1935 Arneson and Stewart described the response of tumor to irradiation as swelling of the tumor cells, ballooning degeneration or pyknotic degeneration and fragmentation of the nuclei, progressive cytoplasmic opacity and acidophilia, a tendency to cornification and finally necrosis and leucocytic infiltration often followed by foreign body giant cell reaction.

MATERIAL

The material for this study comes from three sources: the Tumor Clinic of the Massachusetts General Hospital, the private practice of Dr. J. V. Meigs, and the Pondville Hospital of the Massachusetts State Department of Public Health. We are reporting 206 cases of cervical carcinoma treated by x ray or radium or both and studied by means of vaginal smear. The cases include patients recently treated and followed during treatment and also those who had treatment from 6 months to 15 years before the first vaginal smear was taken. The group is divided pathologically into 27 cases of adenocarcinoma and 179 cases of epidermoid carcinoma. The majority of the epidermoid carcinomas are classified as grade III, although the study includes cases from all 4 grades.

The radiation in these cases necessarily varies since the group includes patients treated over the past 15 years, and both the amount of x ray and radium given and the method of administering the dose has changed considerably during this length of time. Most of the patients were considered to have had full therapeutic doses except for a small number who were given palliative therapy. In the recent cases with rare exceptions the patients have been treated with the 1200 kilovolt x ray machine.

The effect of radiation on the cells of the cervical and vaginal mucosa in patients with carcinoma of the cervix is striking. However, to appreciate fully the changes seen in the vaginal smear it is necessary to have a working knowledge of the cytology of the normal vaginal smear and also the cytology of the malignant cells as seen in the vaginal secretion. It will be helpful perhaps to describe again the cells of the normal vaginal smear. For a more detailed description the reader is referred to the monograph of Papanicolaou and Traut and to our previous publications (7, 8).

The basal cells come from the deepest layer of the vaginal mucosa. They vary in size depending on their position in the basal layer. The inner layer basals are small round cells,

Fig. 12. Abnormal vacuolization of basal cells.

and 30 of epidermoid carcinoma of the cervix. One patient received only radium therapy and 8 only x ray. The remaining 26 received both x ray and radium and in every instance the radium was preceded by a course of x ray. The x ray treatment was given to 25 by 1200 kilovolt therapy and to 9 by 200 kilovolt therapy. One patient received only 4800 r from the 1200 kilovolt machine, the remainder receiving a dose of approximately 6000 r.

Two cases of bladder carcinoma with no uterine neoplasm have been included in this group as controls. The x ray fields used in the treatment of carcinoma of the bladder are similar to those used for cervical carcinoma. Thus, we were able to study the effect of radiation on the normal cells of the vaginal and cervical mucosa uncomplicated by the presence of malignant cells.

The patients followed during radiation treatment fall into 2 distinct classes. Class 1 shows definite radiation reaction in all cells. Class 2 shows very little effect in any type of cell either normal or malignant. The possible prognostic significance of these differences will be discussed in a subsequent publication.

The changes in the cellular constituents have been noted from day to day following

the beginning of treatment. The first patient studied had daily vaginal smears. However as the study progressed it was obvious that smears taken at 3 day intervals gave an adequate picture of the changes which occurred. The days indicated in the paragraphs below are counted from the beginning of radiation treatment.

Class 1—Radiation Changes In the vagina smear the first effect of radiation is seen in the normal cells. The basal layer of the vagina and cervical mucosa is affected before any of the other cells show changes. The basal cell, both inner and outer, become aberrant (Fig. 9). They lose their characteristic round appearance and become elongated. These cells must be differentiated from the malignant fiber cell. The nucleus in these aberrant basal cells is still a perfectly normal vesicular nucleus. The malignant fiber cell contains an abnormal hyperchromatic nucleus with very distinct clumps of chromatin. This change in the basal cells is occasionally seen as early as the second day of x ray treatment but usually not marked until the 9th or 10th day.

An effect which is seen at the same time as the change in the shape of the basal cells is change in their staining reaction. Many of

adenocarcinoma of the cervix.

Fig. 9

Fig. 9. Group of basal cells showing beginning elongation of the cells.

cur more infrequently than either of the other two types. They are large cells approximately the size of precornified cells, which have many oval smoothly granular nuclei arranged peripherally (Fig. 5).

The malignant cells as encountered in epidermoid carcinoma of the cervix are of two types, differentiated and undifferentiated depending on how adult the tumor is. The undifferentiated cells are usually smaller than the inner layer basal cell. They have a hyperchromatic nucleus which shows an apparent increase in chromatin material. The cytoplasm consists either of a very narrow rim or an indistinct background. If seen in groups the nuclear size variation is great, and the cellular borders indistinct (Fig. 6). The differentiated cells assume bizarre shapes. They may be the so called tad pole form which show a long thin tail of cytoplasm and a distinct head containing the nucleus. This type is seen rarely. Another type is the fiber cell. This cell is extremely elongated and thin. The nucleus still appears hyperchromatic but it is elongated. These cells closely resemble muscle fiber cells except for their nuclei which are distinctly abnormal (Fig. 7). In the differentiated cells the cytoplasm is usually adequate but it is abnormally distributed.

The malignant cells seen in adenocarcinoma are undifferentiated. They usually occur in tight groups in which the individual nuclei are piled upon one another. Definite cellular borders are difficult to distinguish. Their cytoplasm is a thin rim which may contain vacuoles which are usually small (Fig. 8).

In attempting to study the changes seen in the vaginal smears of women treated with radiation for carcinoma of the cervix the cases have been divided into four groups. The first group includes those patients who were studied by vaginal smears during their x-ray and radium therapy. The second group includes those with follow ups beginning from 1 to 6 months after treatment. The third group is composed of those patients whose follow-up began at 6 months to a year following treatment. The fourth group are those patients whose treatment took place a year to fifteen years before the first vaginal smear was taken.

THE EFFECT OF RADIATION ON CELLS AS SEEN IN THE VAGINAL SMEAR DURING TREATMENT—FIRST GROUP

Thirty five patients with cervical carcinoma have been studied during their course of radiation treatment. There are 4 cases of adenocarcinoma, one of undifferentiated carcinoma

Fig 16.

treatment had been carried out.

Fig 18. Superficial cell showing polymorphonuclears in the cytoplasm.

not marked until the fifteenth day and increases progressively after that. The cells contain tremendous vacuoles which almost completely fill the cell (Fig 12). Some of the cells may have smaller vacuoles containing polymorphonuclear leucocytes in the vacuole. This sequence is not so commonly seen in the basal cells, however as in the precornified.

The last change to occur in the cells of the basal layer is the appearance of very bizarre forms. The cells may be almost any shape. They are usually of the blown up type so the shape is even more striking (Fig 13). This change is much more pronounced than in the aberrant forms mentioned earlier. The cells may assume dumbbell shape, elongated forms and tadpole forms. These cells must also be distinguished from the differentiated malignant cell. The nucleus is the distinguishing characteristic. It is large but is smoothly granular and not hyperchromatic, or is very small and pyknotic.

It is important to point out that the changes in the basal cells here noted are seen only if the control smear before treatment presented basal cells as part of the cell population. If the woman is premenopausal few basal cells are found and the radiation changes seen first are in the precornified cells to be described

The precornified cells also exhibit change after radiation. The first reaction to occur in this layer of cells is an increase in size. The become two to three times the size of a normal precornified cell. The cytoplasm and the nucleus increase correspondingly so that the cytoplasmic nuclear ratio is undisturbed (Fig 14). This effect has been seen as early as the third day of radiation and as late as the forty fifth. However on the average it is apparent about the fifteenth day of treatment.

At about the same time as this increase in size takes place there are beginning changes in the nuclei of the precornified cells. At first the only change is one of size, but very soon the chromatin structure of the nucleus begins to show degenerative changes. Their nuclei become dark, wrinkled with little structural detail. The nucleus has a dead pyknotic look despite its abnormal size. The nuclear borders are not smooth but very irregular and oftentimes the nucleus has contracted sufficiently to leave a space previously occupied by the full sized nucleus. Occasionally although it is not so often as in the basal series the nuclei will become fragmented and will appear only as small dark particles. The nuclear borders have completely disappeared. Two three or four nuclei are not uncommon in these p

cells of the basal layer change from a basophilic stain to a brownish stain¹. This does not occur in all the cells but is a frequent enough occurrence to be a distinct effect. This difference in staining reaction is probably an early sign of degeneration of the cell.

The subsequent changes are primarily in the nucleus of the basal cells. The nuclei become very degenerate. The nucleus may appear as one small pyknotic dot. Often the nuclear membrane disappears and the nuclear material is collected into discrete black clumps, an actual karyorrhexis of the nucleus (Fig. 10). This type of degeneration will occasionally be mistaken for mitoses if care is not taken. A cell in mitosis shows chromatin in fine threads or very small clumps rather than three or four structureless dots. These degenerative changes usually take place from the 10th day of treatment and increase throughout the course of treatment. It should be noted that this reaction in the nuclei of the basal cells is not characteristic of radiation alone. The same degeneration is often seen in advanced atrophy of the genital tract.

Beginning usually around the twelfth day the most striking effect of radiation on the

cells of the basal layer is seen. There is a great increase in the size of the cells. They become three to four times their normal size. The change is similar to the ballooning of cells which has been described in histological sections following radiation treatment. It is important to realize that these "blown-up" cells show no change in the cytoplasmic nuclear ratio. It remains constant. The nucleus and the cytoplasm, have increased in the same proportion (compare Figs. 1 and 11). The nucleus in one of these large cells is even more finely granular than in the normal. It has a very smooth, speckled appearance in most instances. One should be careful that cells of this kind are not called normal precornified cells. The total size of the cell is often that of precornified cells. Two criteria point to their origin in the basal layer. First, the cytoplasm does not have the true transparency of precornified cells; second, the nucleus is much too big for a normal precornified cell. We have never seen this tremendous ballooning of cells except in smears from a radiated patient.

Another specific change in the basal cells is abnormal vacuolization of the cytoplasm. This usually occurs in cells which have increased in size and is a late effect. It is usually

¹All smears were stained by Papankolou's method. The directions for staining and the counterstains of the smears may be found in the monograph by Papankolou and Treat or in our first publication.

gated in some instances stretching across a high dry field. Others may assume tremendous tadpole shapes. Some have long fibers stretching out from the cell almost resembling pseudopodia (Fig. 17).

The last change to occur in the precornified layer is the appearance of polymorphonuclear leucocytes in the cells. This takes place usually around the 20th day of treatment. It has been seen as early as the 10th and as late as the 31st. It is important when looking for this change to be sure that the polymorphonuclear leucocytes are in the cells and not merely on top of the cells. The leucocytes are very numerous often in postirradiation smears and often they clump on a cell almost obscuring the cell beneath them. This takes place early in the course of treatment. However the actual inclusion of leucocytes within epithelial cells is a later change (Fig. 18).

The cornified cells exhibit all the evidence of postirradiation reaction which are seen in the precornified cell except for the changes in the nuclei. Since the nuclei of cornified cells are originally pyknotic very little change takes place there. The other changes noted apply to the cornified cells as well as to the precornified cells. It should be noted that in radiation smears the precornified cells do not always have a basophilic staining cytoplasm. They very often take an acidophilic stain. As in normal cells the nucleus is the distinguishing characteristic.

A great increase in polymorphonuclear leucocytes is seen very often in the immediate postirradiation smears. In all but 3 of the cases the leucocytes increased markedly. In some cases they increase so much that interpretation of the smear is quite difficult since the leucocytes obscure much of the picture. In 3 cases the increase was due to lymphocytes rather than to polymorphonuclear leucocytes. The increase in leucocytes is variable in the time it appears. It may occur immediately after treatment is instituted or it may not occur until much later.

There is some literature on the occurrence of eosinophils in sections of cervical carcinoma. Gill in 1944, reported that 77 per cent of all epidermoid carcinomas of the cervix had a marked eosinophilia in the tumor. He

believes this may be regarded as of favorable prognostic significance. Unfortunately in vaginal smears the polymorphonuclear leucocytes are so seldom completely preserved that differentiating between types is usually impossible. One of the cases followed during treatment showed a tremendous number of eosinophils. In all other instances no differentiation could be made as to the type of leucocyte.

An increase in small histiocytes usually follows the increase in leucocytes. The time factor is variable but they appear usually 3 to 5 days after the increase of leucocytes. This increase in small histiocytes was seen in all but 3 of the cases. The response of the phagocytic and foreign body giant cells is variable. A marked response of the phagocytic type was seen in 3 cases and foreign body giant cell reaction in 2.

Evidence of some blood is usually seen in positive smears before radiation. It is a variable factor after treatment is instituted. In some cases the bleeding will stop and the smear be free of any blood. Others show fresh blood, fibrin or blood pigment.

Class 1: Radiation Effect in Malignant Cells

The malignant cells show pronounced radiation effect as well as do the normal cells of the vaginal and cervical mucosa. The time of the appearance of definite radiation reaction in these cells varies from patient to patient. The malignant cells all show radiation changes usually by the eleventh day of treatment but occasionally the cells will appear radiated as early as the 8th day. Other cases may not show the complete effect until as late as the 17th day of radiation.

Radiated malignant cells show a good many changes similar to those seen in the normal cells. They increase in size, occasionally as much as four times. Their cytoplasm becomes vacuolated. This vacuolization is especially striking in the small undifferentiated tumor cells which have little cytoplasm. The thin rim of cytoplasm becomes puffed out eccentrically with vacuoles which in some instances are larger than the nucleus (Fig. 19). The radiated malignant cells often contain more than one nucleus, and in many cases may appear as giant cells with 6 to 7 nuclei. pro!

Fig. 22. A sheet of basal cells seen when vaginal smear is difficult to obtain.

cornified irradiated cells. These multinucleated cells may have the blown up vesicular type of nucleus or a degenerate one. The presence of more than one nucleus is probably evidence of an amitotic division stimulated by radiation.

At the same time that nuclei begin to exhibit signs of degeneration the cytoplasm also shows evidence of degeneration. The first degenerative sign in the cytoplasm is the appearance of very fine fibers which may occur in concentric circles around the nucleus or may run from the nucleus to the cell border.

The most striking effect is the vacuolization. The vacuoles may be very large, occupying the greater part of the cell (Fig. 15).

An effect which occurs immediately after the increase in size of the cells and the change in the nuclei is the appearance of precornified cells of queer shape. These bizarre cells are seen occasionally as early as the 6th day of treatment but usually do not appear until later around the 18th day. The cells are even more striking than the bizarre basal cells due to their size (Fig. 16). They also may assume any shape. Some become tremendously elongated.

The number of cells showing increase in size vacuolization bizarre shape and invasion of the cytoplasm by leucocytes rapidly diminishes. Two months after treatment an occasional cell showing these changes is seen. By 3 months such cells are even more difficult to find and in many instances the specific effects of radiation have disappeared by this time. The cornified and precornified are either completely normal or occur in groups without clear nuclear borders. As might be expected the nonspecific changes seen in the basal series persist for a much longer period. No definite time limit has been found for this effect to disappear. The basal cells have large active vesicular nuclei and often a vacuolated cytoplasm. They may have a normal round contour or be aberrant, assuming an elongated form. Leucocytes and histiocytes may or may not be present but usually the smear has a much cleaner appearance than seen earlier.

Thirty-two patients (27 with epidermoid carcinoma, 4 with adenocarcinoma and 1 with adenocanthoma) showed little or no reaction to radiation in the epithelial cells of the vaginal smear. The response in the malignant cells was variable. Fourteen patients showed a disappearance of the malignant cells while the remaining 18 showed persistent cancer cells. The smears usually show perfectly normal or degenerate cornified and precornified cells and a rare active basal cell. This is similar to that seen in the first group class 2.

THE EFFECT OF RADIATION ON CELLS AS SEEN IN THE VAGINAL SMEAR SIX MONTHS TO A YEAR AFTER TREATMENT—THIRD GROUP

The 19 patients included in this group are those whose follow up by vaginal smear began 6 months to a year after radiation treatment was finished. This group necessarily overlaps the previous group somewhat in time element.

Eleven (10 epidermoid carcinoma and 1 adenocarcinoma) out of this group show the expected picture. The vaginal smear consists of perfectly normal or degenerate (cellular borders not distinct) cornified and precornified cells, and aberrant basal cells with active vesicular nuclei. Small histiocytes and leucocytes are present but in variable numbers. Four patients showed foreign body giant cell

reaction. All the specific effects of radiation have disappeared by this time.

Four patients (3 with epidermoid and 1 with adenocarcinoma) show no reaction of any kind. The smears are perfectly normal ones and any distinguishing characteristics are absent.

There are 4 patients (3 with epidermoid carcinoma and 1 with adenocarcinoma) who showed aberrant basal cells increase in polymorphonuclear leucocytes evidence of blood and malignant cells. These of course are postradiation recurrences. It is difficult to see any difference between these 4 and the rest of the group except for the presence of malignant cells. The epithelial cells in these smears are aberrant basal cells with active vesicular nuclei.

THE EFFECT OF RADIATION ON CELLS AS SEEN IN THE VAGINAL SMEAR FROM ONE TO FIFTEEN YEARS AFTER TREATMENT—FOURTH GROUP

The 102 patients included in this group have been followed by vaginal smear beginning at 1 year to 15 years after treatment by radiation. It is in this group that the radiation has varied more than in previous ones since the time interval is of much longer duration. Radiation treatment has varied considerably during the past 15 years so necessarily the cases are not exactly comparable to the first three groups described. However they are an interesting group in which to study the prolonged effects of x ray and radium on the cells of the vaginal and cervic mucosa.

Twenty-nine of these patients were given radium alone and these include all those whose follow up is longer than 10 years. These are included in the groups to be described since they show no distinguishing characteristic.

This group of cases falls into three separate categories if divided by the type of cell found in the smear. Approximately one third of the cases show only basal cells, one third precornified cells and basal cells, and the remainder cornified precornified and an occasional basal cell. This is not an age difference since the three groups do not differ significantly in age.

ably again evidence of abnormal division stimulated by radiation (Fig 20). The appearance of the nucleus is not that of the heavy granular unirradiated malignant cells but rather it is one of complete pyknosis. The nuclei appear dead rather than active. Usually no nucleolus can be made out.

It is often very difficult to say whether a radiated cell was originally malignant or benign. This is especially true of the differentiated malignant cells seen in cervical epidermoid carcinoma. The bizarre cells of both the basal and intermediate layer still have more cytoplasm surrounding the nucleus than do the true differentiated malignant cells. The nuclei of the bizarre basal and precornified group are much more apt to have a washed out smooth appearance than a hyperchromatic pyknotic one.

Nearly half of the cases described in this group showed an increase of malignant cells after radiation had begun. The time of the increase varied from 3 to 21 days and averaged 9. The remainder of the cases showed a progressive decrease in malignant cells until their final disappearance. It is perhaps interesting to note that 1 of the 2 cases of adenocarcinoma of the cervix in this group showed persistence of malignant cells although they did appear radiated. The cells did not disappear until radium treatment was given. On the average however the malignant cells have disappeared by the 24th day after radiation has begun.

Class 2—Little Radiation Change. Not all cervical carcinomas treated by radiation show the change described for the class 1 type of patient. Of the 22 cervical tumors included in this group followed during x ray treatment, 8 showed a different picture. Six cases were epidermoid carcinoma of the cervix: 1 a papillary adenocarcinoma, and 1 an undifferentiated carcinoma.

Two patients were given palliative doses of x radiation (4200 r and 2800 r) and no radium. As might be expected these patients showed very little change in any of the cells. Typical unaffected cells persisted during treatment. They showed little evidence of having been affected by x ray. One of these patients given only palliative therapy showed

no effect of radiation at all in the normal cells, and the other only a very slight response at the end of 22 days.

One patient was treated by radium alone (4700 mgm hrs). The smears from this patient did show a disappearance of the malignant cells but no change in the normal cells.

The remaining 5 cases had over 6000 r of x ray and in addition at least 2400 milligram hours of radium. Of these cases 2 show persistent unirradiated malignant cells, while 3 had carcinoma cells persisting longer than usual and none of these cells showed any definite change. The smears from these patients contain only a rare normal cell showing radiation reaction though in these cases the therapy was adequate.

As a control the vaginal smears of 2 cases of bladder carcinoma treated by radiation and uncomplicated by any uterine neoplasm have been studied. The normal cells in the vaginal smear show the same radiation changes as described for the class 1 type of case, and the changes took place at approximately the same time.

THE EFFECT OF RADIATION ON CELLS AS SEEN IN THE VAGINAL SMEAR IMMEDIATELY AFTER TREATMENT TO SIX MONTHS—SECOND GROUP

The 50 patients included in this group are those whose follow up began immediately after treatment or within 6 months. None of these patients were followed during their treatment and for this reason they have been segregated from the first group though a good many of the changes described previously are seen in this group also.

Eighteen cases (15 of epidermoid carcinoma and 3 of adenocarcinoma) presented moderate to marked reaction to radiation as shown by the cells in the vaginal smear. A reaction was considered as moderate if over half the epithelial cells showed radiation change and the malignant cells had disappeared. A reaction was called marked if it was difficult to find any cells not showing radiation reaction. The reaction is identical with that described for the class 1 type in the first group.

The striking effect of radiation on the cells of the vaginal secretion is not a lasting one.

encountered after irradiation. A good many of the normal cells also show division of the nucleus with no division of the cell.

Frola emphasizes the fact that after radiation there is a subsequent maturation of the undifferentiated cells to mature cells with sharp nuclear borders. We have not interpreted any cells in this light. The bizarre shaped cell, which in an untreated carcinoma might be classified as a differentiated malignant cell, has been interpreted rather as a normal cell which has been so affected by radiation as to be almost indistinguishable from an unirradiated differentiated malignant cell. This may be a mistake in interpretation but it is made on the basis that the cases of bladder carcinoma showed these bizarre cells although there were no malignant cells present in the genital tract. We have concluded that their unusual shapes, nuclear and cell size increase and in occasional instances, the hyperchromatic but pyknotic appearance of the nucleus is due rather to radiation effect on normal cells than to any maturation process stimulated by radiation. It is for this reason that it has become the policy of our laboratory not to call postirradiation smears positive unless typical healthy undifferentiated malignant cells are seen. To one unfamiliar with radiation changes the bizarre cells and the queer pyknotic, huge nucleus of the irradiated normal cells will often be confusing and lead to an error in diagnosis.

Frankle and Amreich have described the swelling of cells during radiation therapy. This is very evident in vaginal smears. The size increase of cells both normal and malignant is very conspicuous. These same authors mention vacuolization of the cells. This effect is also seen in vaginal smears. It is one of the responses seen in marked reaction of the cells to irradiation. Frola, and Arneson and Stewart mention the increased leucocytic reaction and the foreign body giant cell response of the cervical tissue to roentgen therapy. These reactions have both been described here as they are seen in the vaginal secretions from irradiated cervical malignancy.

It is evident that the correlation of the numerous changes seen in the past in the study of irradiated cervical cancer by biopsy

and the changes seen in the vaginal smear are quite comparable. The pyknosis and degeneration of the nuclei, the swelling and vacuolization of the cytoplasm, the evidence of abnormal mitoses and finally the leucocytic infiltration and foreign body giant cell reaction are all seen in the vaginal secretion as they are in the biopsy material. The vaginal smear is a much simpler way of studying the reaction of both tumor and normal cells. It is difficult to do serial biopsies on treated patients. Toward the end of treatment the biopsy may show only necrosis and no viable tissue thus making interpretation impossible. The vaginal smear on the other hand is obtained with great ease as often as desired, for the whole course of treatment. It has the additional advantage of giving possibly a more accurate picture since the entire cell population of the cervix and vagina is represented not merely that of one specific area. The vaginal smear represents a unique and possibly important method of studying radiation reaction in cervical carcinoma.

SUMMARY

Two hundred and six cases of cervical carcinoma in which patients were treated by radiation have been studied by vaginal smear. Both immediate and late changes in the cells in the vaginal secretion have been described. Correlation with studies by biopsy have been discussed. The applicability of this method for study of radiation effect in cervical carcinoma has been suggested and emphasized.

The smears which show basal cells alone have three variations. They may consist entirely of enlarged degenerate cells sometimes seen in normal atrophic smears of menopausal women (Fig. 21). These are basal cells whose nuclei are degenerate and large. The staining reaction of the nuclei is not even and often has a blotchy washed out appearance. The cytoplasm also stains irregularly. This is not diagnostic of radiation but is seen as well in the atrophic smears from normal postmenopausal women. Another type of smear seen is one in which all the cells are aberrant and have large vesicular nuclei. The cells have elongated forms occasionally with rather long tails. It is often difficult to find any normal round basal cells. These queer forms are one of the most difficult types to distinguish from malignant cells. The nuclei of these cells, though active are rarely as hyperchromatic as malignant nuclei. The third type is a smear in which sheets of basal cells are seen. The cells do not shed singly but come off in great clumps. These may be very confusing since at first glance especially when cell borders are indistinct, they are not unlike cancer cells except for their regularity in size (Fig. 22). These cell groups usually occur when the smear has been difficult to obtain. If an attempt is made to secure a vaginal smear when the mucous membrane is very dry and atrophic, the pipette is apt to aspirate cells from the mucosa directly and not those cells which have been shed previously. This smear is not representative of the vaginal secretion. A small percentage of patients after radiation have no vaginal secretion. If secretion cannot be obtained with ease it is perhaps better not to attempt to get a smear.

Of this fourth group approximately one-third show only precornified cells and basal cells in the vaginal smear. The cells may appear perfectly normal or they may be degenerate with indistinct cellular borders. Cornified cells may also be present. However it is very rare (3 of the smears of this group) to see a normal smear of precornified and cornified cells thus long after radiation.

Leucocytes are seen in this group of post radiation smears, but their numbers are variable. Small histiocytes occur frequently. No

evidence of foreign body giant cell reaction was seen. Fresh blood is encountered occasionally and is probably due to the breaking of small adhesions in the vagina. Blood pigment is a much more infrequent finding.

Eight of these 102 patients represent recurrence of their original disease. Five show typical undifferentiated carcinoma cells with no evidence of radiation reaction in the normal cells. Three show undifferentiated malignant cells and very active basal cells. The malignant cells are as those described for unirradiated undifferentiated cells. They show no evidence of having originated from a tumor previously radiated.

DISCUSSION

The changes seen in the individual cells, both normal and malignant, which are desquamated into the vaginal secretion are quite comparable to those previously described by many authors in the study of biopsy specimens from irradiated patients. Of course there are some differences since in a study of the vaginal smear a representative group of all types of cells is seen, while a biopsy is limited to that area which has been removed. Another distinguishing factor between the two methods is that the vaginal smear deals only with the cells on the surface while the biopsy shows the changes much deeper.

Dustin, Frola, and Arneson and Stewart all have described the pyknosis of the nuclei of the cells in biopsy material from patients with carcinoma of the cervix. Pyknosis of the nuclei is marked in the radiation response as seen in the vaginal smear. The cells from the basal layer show a marked pyknosis which often is one of the prolonged effects and among the last to disappear.

Dustin, Meligs and Parker (6) and Frola emphasize the atypical mitoses which occur in the malignant cells during treatment. Mitoses are rarely seen in the vaginal smear. This is true not only of the irradiated cases but untreated cases as well. Whether cells in mitosis go on to complete the division after being desquamated or whether the majority of the cells in mitosis are deep and not likely to slough is not known. Evidence of abnormal mitoses is seen in the vaginal smear in the abnormal malignant giant cells which are often

encountered after irradiation. A good many of the normal cells also show division of the nucleus with no division of the cell.

Frola emphasizes the fact that after radiation there is a subsequent maturation of the undifferentiated cells to mature cells with sharp nuclear borders. We have not interpreted any cells in this light. The bizarre shaped cell, which in an untreated carcinoma might be classified as a differentiated malignant cell, has been interpreted rather as a normal cell which has been so affected by radiation as to be almost indistinguishable from an unirradiated differentiated malignant cell. This may be a mistake in interpretation but it is made on the basis that the cases of bladder carcinoma showed these bizarre cells although there were no malignant cells present in the genital tract. We have concluded that their unusual shapes, nuclear and cell size increase and in occasional instances, the hyperchromatic but pyknotic appearance of the nucleus is due rather to radiation effect on normal cells than to any maturation process stimulated by radiation. It is for this reason that it has become the policy of our laboratory not to call postirradiation smears positive unless typical healthy undifferentiated malignant cells are seen. To one unfamiliar with radiation changes the bizarre cells and the queer pyknotic, huge nucleus of the irradiated normal cells will often be confusing and lead to an error in diagnosis.

Frankle and Amreich have described the swelling of cells during radiation therapy. This is very evident in vaginal smears. The size increase of cells both normal and malignant is very conspicuous. These same authors mention vacuolization of the cells. This effect is also seen in vaginal smears. It is one of the responses seen in marked reaction of the cells to irradiation. Frola, and Arneson and Stewart mention the increased leucocytic reaction and the foreign body giant cell response of the cervical tissue to roentgen therapy. These reactions have both been described here as they are seen in the vaginal secretions from irradiated cervical malignancy.

It is evident that the correlation of the numerous changes seen in the past in the study of irradiated cervical cancer by biopsy

and the changes seen in the vaginal smear are quite comparable. The pyknosis and degeneration of the nuclei, the swelling and vacuolization of the cytoplasm the evidence of abnormal mitoses, and finally the leucocytic infiltration and foreign body giant cell reaction are all seen in the vaginal secretion as they are in the biopsy material. The vaginal smear is a much simpler way of studying the reaction of both tumor and normal cells. It is difficult to do serial biopsies on treated patients. Toward the end of treatment the biopsy may show only necrosis and no viable tissue thus making interpretation impossible. The vaginal smear on the other hand is obtained with great ease as often as desired for the whole course of treatment. It has the additional advantage of giving possibly a more accurate picture since the entire cell population of the cervix and vagina is represented not merely that of one specific area. The vaginal smear represents a unique and possibly important method of studying radiation reaction in cervical carcinoma.

SUMMARY

Two hundred and six cases of cervical carcinoma in which patients were treated by radiation have been studied by vaginal smear. Both immediate and late changes in the cells in the vaginal secretion have been described. Correlation with studies by biopsy have been discussed. The applicability of this method for study of radiation effect in cervical cancer has been suggested and emphasized.

THE EFFECT OF RADIATION ON VAGINAL CELLS IN CERVICAL CARCINOMA

II The Prognostic Significance

RUTH M. GRAHAM B.S. Boston, Massachusetts

A SIMPLE method of determining what effect radiation has on carcinoma of the cervix during and immediately after treatment would be of great practical value. The present methods of evaluating results are exceedingly cumbersome. Most advances in roentgen therapy of this disease have been determined on the survival rates of a certain group of patients as balanced against another group treated differently. If a method could show that at the end of treatment a satisfactory or unsatisfactory result could be expected, instead of the necessity of waiting for a 5 year survival rate the number of cures might be appreciably increased by modification of the present methods of treatment. We believe that the study of the response of cervical tumors to radiation treatment by means of vaginal smear may represent a method of practical value in the early prognosis of cervical cancer.

Many studies have been done in an attempt to correlate biopsy data with possible prognostic value. In 1936 Warren Meigs, and associates published a series of 70 cases of carcinoma of the cervix studied by means of repeated biopsies during radiation treatment. They found that if the tumor showed marked radiation effect and there were changes in the stroma consistent with radiation reaction the survival rate was increased. If however the tumor showed little effect and the stroma little or none the patients did very poorly.

Other authors have attempted to correlate the grade of tumor with the clinical response. Stewart and Farrow in 1940 reported that there was a marked difference in the response to x ray and radium of the same grade tumors. In their opinion single biopsies were not very valuable in judging the actual response. They conclude that a more satisfactory prognosis can be made on the basis of the clinical type of

tumor i.e. the cauliflower growth does much better than the crater like type of lesion.

An interesting study has been reported recently by Glucksmann and Spear. They have attempted to quantitate the radiation response in treatment. The authors emphasize that great care be taken to secure the tissue for biopsy from the growing edge of the tumor. These biopsy specimens were sectioned and areas which showed papillary projections growing into normal tissue were the ones chosen for study. Quantitative counts were done on four types of cells in these areas: (1) the cells in mitosis (2) resting carcinoma cells, (3) differentiating cells (4) degenerating cells. The cells in mitosis disappeared soon after treatment was instituted the resting carcinoma cells persisted longer than the cells in mitosis, but these too gradually disappeared. The differentiating cells increase, finally disappearing after treatment is ended. The degenerating cells increase throughout the treatment and persist for sometime afterward. Thus if the degenerating cells and carcinoma cells are plotted against the days of treatment a graph is obtained in which the two lines cross since as the degenerating cells increase the carcinoma cells disappear. In an unfavorable response the carcinoma cells both in mitosis and those resting remain, and the degenerating cells do not increase giving a graph where the lines are parallel.

In a previous publication the effect, both immediate and prolonged of radiation on the cells seen in the vaginal secretion of patients with carcinoma of the cervix has been described. In this paper an attempt has been made to correlate these findings with the clinical picture and the end result of treatment.

Of the 206 cervical carcinomas studied in the previous paper only 73 whose follow ups were of sufficient length of time (first and

second groups) are included in this study. The changes seen during and immediately following treatment are the important ones as far as any prognostic value is concerned. As yet no correlation has been obtained in the appearance of the vaginal smear months or years after treatment.

In our first paper on the changes due to radiation as seen in the vaginal smear we described the cases followed during and immediately after treatment as falling into two definite classes. The first class is that which shows the following changes. The normal cells the basal cells first increase in size then show signs of degeneration and toward the end of treatment, show marked degenerative changes such as vacuolization of the cytoplasm and marked pyknosis or karyorrhexis of the nuclei. The precornified cells show the same changes though these occur later than those seen in the basal layer. The degeneration of the nucleus is not as prominent in the precornified cells as in the basal. The nuclei of the precornified cells often have a smooth washed out appearance. The cornified cells increase tremendously in size and there is much cytoplasmic degeneration but since the nuclei of these cells are originally pyknotic there is no

Chart 2. A poor response to radiation (Case 10 in Table IV). There is very little diminution in the number of malignant cells seen and the normal epithelial cells show only a slight response to radiation.

change there. The smears usually show a progressive leucocytosis and an increase in small histiocytes. Occasionally phagocytic histiocytes appear and in a few cases foreign body giant cells were seen. Malignant cells these usually persist until the tenth or eleventh day of treatment. They sometimes increase in numbers and then disappear but more often show a gradual decrease. The time of their disappearance is unimportant. More important is the gradual decrease. The malignant cells of class I show pronounced radiation changes. They are often multinucleated giant cells probably evidence of amitotic division. They show the same degenerative changes as described for the normal cells: increase in size, vacuolization and finally a smooth washed out appearance to the nucleus, pyknosis or a complete breaking up of nuclear material.

Chart I shows a typical case which falls into class I. The approximate percentage of normal cells showing radiation reaction and the approximate percentage of malignant cells present whether healthy or irradiated are plotted against the days of treatment. It is important to note that the chart is *approximate* and does not represent absolute quantitative data. It is difficult to do accurate cell counts on vaginal smears since many fields are too thick to count individual cells and only thin areas could be used. The chart merely

Chart 1. A good response to radiation (Case 6 in Table III) showing a complete disappearance of malignant cells by the 18th day and a maximum radiation effect in the normal cells by the 33rd day. It should be noted that the percentage of malignant cells is based on a scale in which 100 per cent equals the maximum incidence of these cells encountered in any of the smears on this case, while the radiation effect is based on 100 per cent equaling a response in all normal epithelial cells.

good results. Of these 28 patients are living and well with no evidence of persistent disease or recurrence. Five patients are dead. We have been unable to follow 3 patients. We show the good response group divided by clinical stage of disease.

Thirty-seven cases were classified as poor responses. Of these 16 are dead, 8 have persistent disease or recurrence and 3 are living. Of these 3 have not been examined during the past year but they are known to be alive. Whether they have persistent disease or not is of course in doubt but we have classified them as well. Table II shows the poor response group divided by clinical stage of the disease.

If Tables I and II are compared it will be readily seen that there is correlation between the prognosis by vaginal smear and the clinical stage of the disease. Both the groups in stage I and stage IV are too small to be of a great deal of significance. However, they are reversed as to prognosis both by vaginal smear and clinical response. Stage II shows a majority of the cases in the good response groups, and in stage III the cases in the poor response group are in the majority.

Tables III and IV give in detail the cases included in this study. The age, duration of

symptoms type and grade of tumor stage of disease amount of treatment biopsies after radiation response by vaginal smear and follow up are all listed.

Though in a series as small as this, statistics of error are not of very great value it is perhaps of interest to point out that if the cases with no follow up are excluded from the series the prognostic accuracy of the vaginal smear in carcinoma of the cervix is 88 per cent. Glucksmann reported an accuracy of between 80 per cent and 86 per cent in a longer series by means of quantitative counts of biopsy material.

It should be mentioned that the follow up on this series is not as long as would be most desirable in a study of this kind. The longest follow up is 3 years and several patients have been followed up less than a year. It is fairly obvious that there may be patients who have been classified as good responses who may yet have recurrences. However the results in the poor response group are such that the length of time of the follow up is less important. This fact for the time being at least would seem to indicate that a greater importance be attached to a poor response than a good response.

DISCUSSION

Many authors have shown that a correlation between radiation response and prognosis could be obtained by studying radiated tissue sections from the growing edge of tumors which have been irradiated confirms the impression that the radiation response in normal and malignant cells is of great importance in the evaluation of the final result of radiation treatment.

The method of biopsy in the study of radiation response is both time consuming and expensive. It is impossible from a practical standpoint in most clinics to make biopsy studies of patients once a week during their entire course of therapy. Furthermore as treatment progresses biopsies are difficult to obtain and during the later part of treatment may show only necrotic tumor if care is not

We feel that the vaginal smear method represents a more practical method for follow

ing patients during radiation therapy. The vaginal smear is easy to obtain. Technicians can be taught easily to take satisfactory smears. Smears may be taken daily if desired. Another distinct advantage of the vaginal smear is that a representative group of all the cells, both normal and abnormal of the vaginal and vaginal mucosa are seen. For this reason the total effect of radiation reaction can be perhaps more accurately determined.

The results as shown by our figures in a series of 73 cases are significant enough in our opinion to suggest to the clinician the vaginal smear as a practical approach to the problem of radiation response of cervical carcinomas. If by a study of the vaginal secretion the immediate response of the tumor to radiation can be determined, the treatment of cervical carcinoma may be made more effective. If a borderline surgical risk and has shown no response to radiation better results might be obtained by re-evaluating the case after radiation and considering radical sur

gery One third of the stage II cases showed no radiation response This is certainly a group of cases in which the salvage rate might be appreciably increased by surgery Some patients may require more radiation to bring about the desired effect, and these could be followed by means of vaginal smear to see if additional treatment would produce reaction in normal and malignant cells

We feel that the study of the radiation response of cervical carcinoma by means of the vaginal smear represents a practical method which will aid in evaluating the effect of treatment on the tumor and will be a useful tool in the prognosis as well as the treatment of this disease.

SUMMARY

Seventy three cases of cervical carcinoma have been studied by means of the vaginal smear during and immediately after radiation treatment for possible prognostic significance They have been classified as good or poor responses The prognostic accuracy is 88 per cent The practical application of the method has been discussed

PATHOLOGICAL PHYSIOLOGY OF BILIARY DRAINAGE

The Use of a New Type of T Tube and the Criteria for its Removal

JOHN M MCGOWAN M.D. F.A.C.S. F.R.C.S. (C)

J KENNETH KEELEY M.D. and FRANCIS HENDERSON M.D.
Boston, Massachusetts

THE importance of exploring the common bile duct at the time of cholecystectomy and of subsequent T tube drainage has been firmly established by many authorities. Prolonged T tube drainage decompresses the biliary tree permitting recovery from cholangitis and pancreatitis. In addition to the therapeutic benefits, the T tube affords a means for studying the pathologic physiology of the biliary and pancreatic systems. These studies are (1) roentgenological (2) manometric, and (3) chemical. Roentgenologically one may detect the presence of hydrohepatosis, a missed stone structure duodenal spasm or pancreatitis. By pressure studies one is able to determine the degree of cholangitis pancreatitis, ampulla edema or spasm. By chemical tests of the T tube bile one can determine the degree of liver damage present. By such means therefore the progress of recovery of the biliary system may be checked periodically and the exact time at which the T tube should be removed can be determined. Previously roentgenograms taken in the anteroposterior position have usually been considered adequate. We however have taken roentgenograms in the lateral position also and have found to our surprise that the type of T tube ordinarily used tends to pull out and a kinking of the common bile duct results. In some cases the common duct was so sharply kinked that obstruction to the flow of bile resulted. Accordingly we have developed a new tube for biliary drainage which avoids kinking of the common duct. It is with the presentation of

this tube and its comparison with the standard type that this paper is chiefly concerned

REVIEW OF LITERATURE

Lahey has written forcefully of the necessity for exploration of the common bile duct. In 1938 he reviewed his cases over a period of 18 years and showed that while the frequency of exploration increased from 15 to 50 per cent, the incidence of common duct calculi apparently increased from 8.4 to 18 per cent. In other words the more he looked for stones the more he found. He also found that in 39 per cent of the cases in which common duct stones were found at operation there was no history of jaundice. An even higher incidence—up to 30 per cent of all of gall bladder stone cases—of calculi in the common duct as well has been reported by others. Data published by Allen and by Walters have been confirmatory. Cutler and Zollinger (4) explored the common duct in 40 per cent of a series of cholecystectomy cases and found common duct calculi in 22 per cent. In a series of cases of choledocholithiasis reported by Judd a history of intermittent colicky pain was found in 98 per cent, jaundice in 65 to 75 per cent. Bile was obtained on duodenal drainage in 83 per cent of these cases. These and many other surgeons have stated that there is little or no increase in mortality when choledochotomy is added to the cholecystectomy operation. Among present day indications for exploring the common bile duct may be listed the following (1) a history of chills and jaundice (2) palpable common duct calculus (3) dilated common duct (4) thickening of the head of the pancreas (5) multiple small calculi or sand in the gall bladder when the cystic duct is large in size (6) a history of calculi recovered from the stools.

A part of the work of this paper was done in Doctor Francis Henderson Laboratory Fourth Surgical Service, Boston City Hospital, Boston, Mass.
From the Surgical Service, Regional Hospital, Camp Joseph T. Robinson, Arkansas, the Boston City Hospital, and Tufts Medical School, Boston, Mass.

While the necessity of common duct drainage has been generally accepted, the duration of the drainage has remained a matter of debate. There is no general agreement as to the proper length of time the T tube should be left in place in any given type of case. Carter found on questioning 6 eminent authorities that there were no established criteria for the removal of the drainage tube. Opinion ranged from 2 weeks in uncomplicated cases to 2 months in cases showing marked cholangitis and evidence of marked obstruction at the time of operation. Few surgeons left the T tube in for longer periods. Some believed that prolonged drainage predisposed to development of persistent biliary fistula or stricture of the common duct. Evidence is accumulating that these conditions very rarely occur in otherwise uncomplicated cases. In the cases which we have studied we have found no evidence of any complications from the use of the T tube. The biliary fistula healed promptly after removal of the T tube in each case provided there was no stricture and the T tube was not removed prematurely. Previously then the optimum time for removal of the common duct T tube has been a matter of personal experiences and opinion therefore a matter for debate. Within recent years we have developed certain physiological tests which we have found useful in determining the optimum time for the removal of the T tube, and we have outlined these tests in previous communications (10-12). They consist of roentgenologic and pressure studies for determination of patency of the common bile duct and the presence or absence of cholangitis. Briefly the T tube is left in until the lower end of the common duct is patent and the cholangitis has completely subsided.

In the presence of obstruction preventing the normal emptying of the biliary tree dilatation occurs throughout the entire system as demonstrated so clearly by Counseller and McIndoe who have shown that the changes involved even the finest biliary radicals resulting in a diffuse process of 'hydrohepatosis.' In previous communications (10-13) we have shown that these anatomical changes have their physiological counterpart as may be demonstrated by the disturbed intrabiliary

pressure relationship. By means of a water manometer previously described (11) we have measured two types of pressure: (a) the resting intrabiliary and (b) the perfusion pain level. (a) The resting intrabiliary pressure, an index of patency of the lower end of the common bile duct, should be 30 millimeters of water or less. (b) The perfusion pain level, an index of common duct sensitivity and hence inflammation, is the lowest pressure at which the common duct can be perfused with saline before discomfort is experienced by the patient. A patient with a common duct free of inflammation can tolerate up to 500 millimeters of water without pain. When there is any obstruction to the flow of bile into the duodenum the resting intrabiliary pressure will be found to be increased. If there is cholangitis present, the patient may experience pain on perfusion with pressures as low as 100 millimeters of water or less. Pressure readings are made 2 weeks postoperatively at which time the resting pressure is frequently found to be elevated and the pain level is often considerably decreased. As a result of the decompressing effect of continued T tube drainage these disturbed pressure relationships slowly change toward normal unless the damage to the liver and ducts has been very severe. This return to normal values may not occur for a long period after relief of obstruction, even as long as 3 months or more.

The injection of a radiopaque substance by way of an indwelling T tube to obtain an exact representation of the contour of the biliary tree has been reported by Mirizzi and others. He reported a series of 400 cases collected over a period of 5 years. His method included the injection of lipiodol at the time of operation into some portion of the bile duct system for the purpose of obtaining an x-ray at once immediate cholangiography. Should an anatomical defect be found Mirizzi explores the common duct. Robins and Hermonson reported 25 cases in which they had made use of this procedure at the operating table preferring lippuran because they found it less irritating. Other series of cases reported not only confirmed the value of this procedure as a determinant for or against common duct exploration, but also called attention to its

SURGERY GYNECOLOGY AND OBSTETRICS

value postoperatively the so-called delayed cholangiography. By these procedures it is possible to demonstrate and differentiate residual calculi strictures spasm of the duodenum, pancreatitis with swelling malignancy of the bile ducts ampulla of Vater or the head of the pancreas. The progress of the biliary tree in its return to normal caliber by decompression of the hydrohepatosis, by relief of obstruction and T tube drainage may also be accurately followed. Various radiopaque substances including thorotrast diodrast brominol lipodol, hippuran and sklodan have been used for cholangiography. We (11) have used sklodan or diodrast injection 15 to 25 cubic centimeters at body temperature into the T tube stopping the delay occurs in taking the x ray picture after the injection. By use of this cholangiographic technique the beneficial effect of amyl nitrite or nitroglycerin to the relaxation of the smooth muscles of the sphincter mechanism of the biliary tract has been demonstrated (10 11 13).

Graham pointed out two decades ago that hepatitis is a constant accompaniment of cholecystitis. Snell has co-ordinated the degree of disturbance of liver function with the anatomical changes demonstrated at an operation. Gray Nettroeur Bollman and ooc of us (McGowan) (6 7) have shown that in many cases of gall-bladder disease bile acid concentration was diminished in T tube bile. The decrease of bile acids was found to parallel the degree of hepatic damage. In addition to the liver damage resulting from the biliary disease there was evidence of marked temporary inhibition of liver function as a result of conditions associated with the operative procedure. This temporary inhibition of liver

function became progressively worse until the fourth to sixth postoperative day when the liver began to recover. In cases in which evidence of permanent liver damage was slight, recovery from temporary postoperative inhibition of liver function was rapid a matter of days. In other cases in which there was evidence of marked permanent liver damage, the postoperative recovery of liver function, was slow in some cases requiring several months. It was found also that a moderately damaged liver does not completely regain its function of concentrating bile acids a fact indicating a limit of repair after injury. This tests appears to be reached usually at the end of the second week, after operation, although improvement may be demonstrated for a longer period especially in cases of severe damage. This recovery was delayed by premature clamping of the T tube. It was felt that T tube drainage should be continued until the recovery of liver function had reached its maximum for that particular case that is until the bile acid concentrating power had ceased to improve.

METHOD OF STUDY

The T tube described is the same as the standard type used except that an inflatable bag is attached approximately 18 centimeters from the cross limb of the "T" according to illustration in Figure 1. This bag is inflated by means of a second tube which is built into the first the arrangement being similar to that used with the Foley tube.

Fourteen patients requiring drainage of the common bile duct were studied.

Criteria which we have used for exploration of the common duct were essentially the same as previously referred to. The common duct was opened longitudinally just below the cystic duct. The size of the incision made should not be greater in length than the diameter of the duct. The lower end of the common duct is usually gently dilated by means of a dilator or catheter. Forceful efforts at dilatation are avoided. Zollinger (18) has shown that forceful dilatation of the ampulla of Vater may result in postoperative edema followed by fibrosis and stricture.

The T tube is inserted by the method shown in Figure 2. The bag is then inflated with sterile saline solution. Two weeks after operation the following tests are made: (1) pressure studies (a) resting intrabiliary pressure and (b) perfusion pain level, and (2) roentgenogram of the biliary tract. Clamping of the tube is then started beginning with 1 hour twice daily. This period is gradually increased by a half hour twice daily until the tube is clamped off all the time. If the studies show elevated resting pressure or a low pain level the clamping of the tube is delayed until pressure levels approach normal. After the T tube has been clamped off continuously for 3 weeks it may be removed provided that: (1) the resting intrabiliary pressure is 30 millimeters of water or less; (2) the pain level is 500 millimeters of water or better; (3) the cholangiograms show absence of pancreatitis stricture or stone. By the technique and apparatus previously described (10, 11, 12) intrabiliary pressure studies were made starting on the 14th postoperative day in all cases reported. Fourteen cases were studied in all. The new type of T tube was used in 6 cases and the standard type of tube in 8.

RESULTS

Of the 14 cases reported, stones were found in 6 (43%) pancreatitis in 1 and common duct pathology consisting of a stricture in 1 case. One showed a stricture of the ampulla of Vater with regurgitation of bile into the pancreas producing pancreatitis which secondarily produced more obstruction of the common duct and jaundice. Of the cases in which the old type of the T tube was used, cholangiograms taken in the lateral position showed kinking of the common bile duct in each case (Figs. 3 and 4). This kinking varied from one of slight degree to one of a very acute type. In 1 case in which kinking of the common bile duct was extreme, there was an elevation of the intrabiliary pressure. This pressure increased as the kinking became greater. The patient complained of considerable pain. The tube finally came out of its own accord in spite of all attempts to keep it in place by means of silk thread. In all cases in which the new type of T tube was used, roentgenograms

Fig. 2. This shows the method of introduction of the T tube into the common bile duct. At the top is shown the manner in which the tube is grasped with a curved hemostat. 1. The margin of the opening into the common duct is grasped on each side with Judd Allis forceps. 2. The T tube is then introduced into the common duct and pushed upward toward the liver until the edge of the lower limb has past the margin of the opening in the duct. 3. The cross-limb of the tube is then pushed toward the duodenum until the "T" is completed. 4. The defect in the common duct is then sutured on the duodenal side of the T tube.

showed slight or no kinking of the common bile duct (Fig. 5). In the patients drained with the old type tube, there was a slight discharge around the tube due probably to continuous friction of movement between the abdominal wall and the tube. In the cases in which the new tube was used, the skin healed completely around the tube and there was freedom from discharge or excessive granulations. In addition, the intrabiliary pressure readings were in general lower than in the patients drained with the conventional tube. In 2 cases, roentgenograms showed the presence of a small stone in the common duct which had escaped detection at the time of

Fig. 3. Common bile duct ampulla of Vater; 4, hepatic duct; 5, point at which common bile duct begins; 6 is intrahepatic; 7, tunnel the duodenum; the portion of the duct between 7 and 8 is intrahepatic; 9, T tube. 4, This cholangiogram taken in the lateral position shows the marked kinking of the duct by means of tension of the lateral position of T tube. 5, This is the same patient with a roentgenogram taken in the anteroposterior position the usual position in which cholangiograms are taken. There is no evidence in this view of the marked kinking of the duct noted in the lateral view.

operation. In each case the stones were made to pass by applying the following procedure: the pressure apparatus was connected to the common bile duct and the perfusion pressure was slowly raised to 700 millimeters of water. The patient was given four deep inhalations of amyl nitrite. This procedure was repeated several times. Subsequent roentgenograms showed that the stones had passed. Of the patients in whom the standard type of T tube drainage was used, 1 made a good recovery, 1 developed a pneumonia postoperatively, 1 made an uneventful convalescence but was later admitted because of severe pain and died from pancreatitis and left ventricular failure. The remainder made an uneventful convalescence. In 1 patient with a stricture of the common bile duct which was drained by the standard tube the tube was pulled out gradually. In the cases of the new type of T tube drainage there were no postoperative complications. In those cases in which the T tube was left in place until all the criteria

referred to were satisfied, there have been no tendencies to fistula formation. On the contrary the wound healed promptly and in no case was there any biliary drainage after 24 hours. Further there has been freedom from late symptoms of biliary dyskinesia or the so-called postcholecystectomy syndrome.

DISCUSSION

Recurrence of symptoms after cholecystectomy are frequently reported. One of the reasons for this is due to the fact that the surgeon while he may pay a great deal of attention to the gall bladder often fails to realize that the biliary tract and the pancreas are frequently involved as part of the same disease. The cholecystectomy should be considered as only a part of the treatment and prolonged biliary drainage should be confirmed when indicated. Drainage should be continued until the chemical, manometric, and roentgenological studies show maximum benefit has been obtained. The resting intrabiliary

Fig. 4 This diagram, drawn to scale from the cholangiogram in Figure 3, shows the marked kinking of the common duct associated with the use of the standard type of T tube.

Fig. 5 This diagram, drawn to scale from a roentgenogram of an actual case, shows the new type of T tube in place with no distortion of the common duct.

pressure determines the patency of lower ends of the common duct. The perfusion pain level is an index of the amount of inflammation within the biliary passages. It is really in ternal palpation. In external palpation we determine the degree of inflammation by applying pressure to the involved parts directly with the hand. In internal palpation of the biliary tract we use the amount of water pressure which the patient can stand as an index of the degree of inflammation in the duct

SUMMARY

1 Cholecystectomy should be considered as only one phase of the treatment of a disease complex which may involve the gall bladder bile ducts, liver and pancreas at the same time. Exploration of the common bile duct should be performed in approximately 40 per cent of cases in which cholecystectomy is being performed.

2 Choledochotomy should always be followed by drainage of the common bile duct by

SURGERY GYNECOLOGY AND OBSTETRICS

means of a T tube. The T tube is used for diagnostic and therapeutic purposes. Diagnostically one is able to determine the presence of a missed calculus cholangitis pancreatitis stricture ampulla edema, or duodenal spasm. The diagnostic tests used are cal analysis of the bile. Therapeutically T tube drainage is continued until cholangitis pancreatitis or ampulla edema has subsided. When T tube drainage has been continued until maximum benefit has been obtained as indicated by prescribed tests there has been no tendency for further symptoms to occur such as those which take place in cases of postcholecystectomy syndrome.

3. X ray films taken in the lateral position have shown that the standard type of T tube tends to be pulled out and a kinking of the common bile duct results. To prevent these undesirable complications a new type of T tube with an attached inflatable bag is described. The benefits of this tube are (1) absence of kinking of the common bile duct (2) a clean wound with freedom from dis-

charge and (3) less tendency for the tube to be pulled out.

CERTAIN PELVIC TUMORS ASSOCIATED WITH ASCITES AND HYDROTHORAX

MARVIN CALMENSEN M D MALCOLM B DOCKERTY M D and
JOHN J BIANCO M D., Rochester Minnesota

A DEFINITE clinical syndrome (Meigs syndrome) consisting of ascites and hydrothorax associated with fibroma of the ovary has been recognized in recent years (2, 6, 11-14, 29, 31, 35, 51, 54, 56, 58). Certain other benign pelvic tumors may now be identified as causing this syndrome which is of considerable importance because it presents a clinical picture usually associated with inoperable malignancy and pleural metastasis. In the group of lesions under consideration almost magical relief is afforded by surgical extirpation of the tumor.

ANTECEDENT STUDIES

The first recorded case of the syndrome, as it is recognized today, was reported by Cullingworth in 1879. His patient a 36 year old widow, was found on physical examination to have two pelvic tumors associated with ascites and bilateral pleural effusion. She died of cachexia, dyspnea, and general collapse. At necropsy the peritoneal and left pleural cavities were filled with fluid. Bilateral tumors of the ovaries were found that on the right measured 12 by 9 by 5 centimeters and that on the left measured 15 by 12 by 7 centimeters. The pathologic diagnosis of the ovarian tumors was bilateral fibromas with cystic degeneration.¹ In discussing his case Cullingworth stressed the importance of the presence of ascitic and pleural effusion inasmuch as up to that time it was thought that any tumor giving rise to such effusion had to be malignant. In 1892 Tait described the syndrome in an article entitled "On the Oc-

currence of Pleural Effusion in Association with Disease of the Abdomen." He cited 2 cases. The first patient presented the typical features of malignant neoplasia with ascites and hydrothorax resulting from secondary deposits. The second by contrast was a 36 year old woman who had undergone repeated tapping for relief of ascites. At operation she was found to have a solid fibroma of the right ovary weighing 2 pounds, 2 ounces (about 1 kgm). Tait remarked, "The lesson in this case is in my opinion a very valuable indication that no set of conditions in the abdomen however apparently unfavourable are sufficient to justify us in an absolutely unfavourable condemnation in any particular case."

Kelly and Cullen in 1909 observed the combination of ascites and hydrothorax in a patient who had uterine leiomyomas. Satisfactory recovery followed hysterectomy. In 1914 Caro mentioned the occurrence of ascites and hydrothorax associated with a giant fibroma of the ovary. In 1923 Owen reported his own case of fibroma of the ovary associated with ascites bringing out the fact that hydrothorax might complicate the aforementioned combination. Two of the patients in the 55 cases of fibroma of the ovary reported by Hoon in 1923 from the Mayo Clinic had unilateral hydrothorax as well as ascites. A single case of an ovarian tumor associated with ascites and hydrothorax was reported by Leo in 1926 but the type of the tumor was not revealed. Wong in 1928 reported a case of ascites and hydrothorax associated with a twisted ovarian cyst. At operation the abdomen of the patient was found to be filled with blood stained fluid. A large hemorrhagic multilocular ovarian cyst, with two complete twists in its pedicle, was removed. The patient made a complete recovery.

Salmon in 1934 reported 2 cases of benign pelvic tumors, each of which was associated

¹From the Division of Surgery, Mayo Foundation, and the Section on Surgical Pathology, Mayo Clinic.

³Cooper, in 1882, observed the frequent occurrence of edema in the tumor substance of fibromas and cystofibromas of the ovary and correlated the presence of edema with the formation of "groides or degenerative cysts."

SURGERY GYNECOLOGY AND OBSTETRICS

with ascites and hydrothorax. One lesion was an ovarian fibroma the other was a fibroid tumor of the uterus. In his book, *Tumors of the Female Pelvic Organs* published in 1934, Meigs (33) described 3 cases from the Massachusetts General Hospital of benign ovarian fibromas associated with hydrothorax and ascites. In 1935 another case of fibroma of the ovary with pleural effusion and abdominal ascites, with complete cure after surgical removal, was reported from the records of the Massachusetts General Hospital (5). In 1937 Meigs and Case published data concerning 7 cases of fibroma of the ovary associated with ascites and hydrothorax. These included the 4 cases from the Massachusetts General Hospital, Hoon's 2 cases from the Mayo Clinic and Leo's case taken from the Italian literature. This was the classical report defining out the possible coexistence of ascites and hydrothorax in the presence of benign fibroma of the ovary and emphasized the importance of recognition of this association. Curability was now offered for a condition that formerly had been thought to have a basis in hopelessly inoperable malignant neoplasia. Rhoads and Terrell, in 1937 summarized 9 cases taken from the literature, of ovarian fibroma with ascites and hydrothorax, and reported a single case of their own. They stressed the fact that this condition constituted a clinical entity and suggested that it should be called a syndrome. Weld reported 2 cases in 1938. In 1939, Meigs (34) reviewed a total of 15 cases taken from the literature, including the original 7 contained in the report of 1937. Subsequent to 1939 reports of ovarian fibroma associated with ascites and hydrothorax have appeared in the literature with increasing frequency (3 3 9 11 12 14 17 28, 35 47). In 1943 Meigs, Armstrong and Hamilton gave a synopsis of 27 cases of fibroma of the ovary in which evidence of signs or symptoms of fluid in the abdomen and thorax had been found in the abdomen and thorax had been found in the abdomen and thorax. Watson, and Taylor added 3 other cases in the discussion of the aforementioned synopsis. Since 1940 other benign ovarian tumors associated with hydrothorax and ascites have been reported. Vogt noted a case of granu-

lous-cell tumor of the ovary associated with hemoperitoneum and hemothorax. Traut and Marchetti, in a study of 54 ovarian tumors of the theca-granulosa cell group stated that in 1 case hydrothorax was a prominent symptom, and that at operation abdominal fluid had been found. MacFee reported a case in which a multilocular cystadenoma of the left ovary weighing 17 pounds (7.7 kgm.) was found to be associated with hydrothorax and ascites. Kelemen recently reported a case in which Meigs syndrome had been caused by a Brenner tumor of the ovary. Perlmutter and Mendel and Tyrone observed the same syndrome in cases of thecoma of the ovary. Rubin and associates reported a similar case, which pseudomucinous multilocular cystadenoma of the ovary was associated with hydrothorax and hydrothorax. Meigs and his co-workers did not include either benign tumors (other than ovarian fibromas) or cancers in their reported series, but stated that when such lesions were found to constitute a large enough group they should be included in the syndrome. Benign tumors as enumerated previously now comprise a sizable group and in some cases cancer also has been reported to be associated with the syndrome. Schenck and Eis reported a case of papillary cystadenocarcinoma of the ovary and Anderson observed Meigs syndrome in a patient who had a malignant cystadenoma of the ovary. Both of the patients in these latter 2 cases recovered after surgical removal of the tumors, indicating that the malignant nature of the tumors in itself was not the cause of the ascites and hydrothorax.

METHOD OF PRESENT STUDY

Records from the files of the Mayo Clinic from 1910 to 1945 were carefully examined for instances of pelvic tumor associated with ascites and hydrothorax (Meigs syndrome). Nine examples of this condition were found among approximately 20,000 records of surgically removed pelvic tumors. An approximate classification of the lesions removed in these 20,000 cases is as follows: 16,000 uterine fibromyomas; 500 ovarian fibromas (this did not include all the smaller fibromas); 1,100

cystadenomas and teratomas and 1 500 carcinomas of the ovary. This gives a total of 19 100. The rest of the tumors constituted a miscellaneous group which included granulosa-cell tumors and other lesions. The incidence of occurrence of this syndrome in this series was 0.05 per cent.

Pathologic material was secured. The tumors were studied in gross detail for pertinent data. Multiple blocks of tissue were then cut from the tumors and placed in a 10 per cent solution of fresh formalin. Sections were cut at a thickness of 10 microns on a freezing microtome and stained routinely with hematoxylin and eosin. The latter provided the material for the microscopic study.

In the present inquiry the 9 cases in question will be reported; then the clinical features will be considered; next the pathologic data will be analyzed; finally the end results of treatment will be presented, followed by comment on the condition in general and by conclusions. The first 3 cases reported in the present paper also were reported by Hoon in 1923. The seventh case was reported by Masson and one of us (9) (Dockerty) in 1944.

REPORT OF CASES

CASE 1. A 36-year-old married woman entered the clinic on July 3, 1917, complaining of bloating of the abdomen. Examination of the thorax revealed dullness and a decrease in fremitus more marked on the left side. The abdomen was distended and a fluid wave was demonstrable. Thoracentesis was performed once. A large mass was attached to the uterus. Roentgenologic examination of the thorax revealed the presence of fluid bilaterally. A large ovarian fibroma about 18 centimeters in diameter was removed surgically.

CASE 2. A 53-year-old married woman entered the clinic on November 26, 1920, complaining of bloating of the abdomen and some degree of interscapular pain. Thoracentesis had been performed twice before she visited the clinic. There were physical signs of fluid in the right side of the thorax. This was confirmed by roentgenologic examination. Abdominal ascites was present. Thoracentesis was performed twice more before the patient was operated on. Surgical exploration revealed a large fibromyoma of the right ovary which weighed 510 grams.

CASE 3. A 59-year-old married woman entered the clinic on September 19, 1929, complaining of progressive enlargement of the lower part of the abdomen of 1 year's duration. Physical examination revealed evidence of fluid in the left part of the thorax. A large pelvic tumor occupied the abdomen and ex-

Fig. 1. Photomicrograph of a section of the ovarian fibroma in Case 3. Marked separation of the tumor cells by edema fluid is shown (hematoxylin and eosin $\times 60$).

tended to the umbilicus. Roentgenologic examination of the thorax showed the presence of fluid on the left side. Abdominal exploration disclosed considerable free fluid in the peritoneal cavity. A solid cystic ovarian fibroma measuring 19 by 10 by 8 centimeters was removed. The tumor weighed 835 grams. A section of it is seen in Figure 1.

CASE 4. A 42-year-old single woman entered the clinic on May 1, 1931, complaining of abdominal enlargement and a nonproductive cough of 6 months duration. Signs of fluid were present in the lower part of the thorax on the right. The abdomen was large and distended. A fluid wave and shifting dullness were demonstrated. Abdominal paracentesis was performed, 13 000 cubic centimeters of clear straw-colored fluid was removed. Pelvic examination revealed an enlarged freely movable uterus. Roentgenologic examinations of the thorax disclosed fluid in the right base. Surgical exploration revealed a large degenerating fibromyoma of the uterus. This was removed. The uterus was not removed. The tumor was 13 centimeters in diameter.

CASE 5. A 49-year-old single woman entered the hospital on March 27, 1933, complaining of dyspnea of 2 months duration. Prior to this entry to the hospital she had been hospitalized elsewhere for 3 weeks. Fluid was found in the right side of the thorax. Thoracentesis had been performed 4 times previously. Examination at the Mayo Clinic showed that fluid was still present in the right part of the thorax. The abdomen was markedly protuberant and shifting dullness was demonstrated. Roentgenologic examination of the thorax showed pleural effusion to be present on the right side. Abdominal exploration revealed a large degenerating tumor of the right ovary measuring 20 by 10 centimeters. Histopathologic examination demonstrated the lesion to be a mixed cylindroid and folliculoid type of granulosa-cell tumor of the right ovary.

CASE 6. A 50-year-old married woman entered the clinic on April 26, 1940, with the report that a tumor

Fig. 2. Preoperative roentgenogram of the thorax of the patient in Case 7. The entire right lung, except for the apex, obscured by fluid.

Fig. 3. Large ovarian fibroma removed from the patient in Case 7, showing a fibrous and edematous cut surface, with a large central cystic and necrotic region.

in the uterus had been discovered 4 months previously. Physical examination of the thorax revealed nothing abnormal, but roentgenologic examination disclosed fluid in the right base. Abdominopelvic examination showed a large multilocular mass. Multiple uterine fibromyomas with diffuse pelvic inflammatory disease were found at exploration. A moderate amount of free fluid was found in the abdomen. Total abdominal hysterectomy, bilateral salpingo-oophorectomy and appendectomy were done.

CASE 7. A 45 year old married woman entered the clinic on November 11, 1943, complaining of dyspnea of 18 months duration. Roentgenologic

examination of the thorax in April, 1943, had revealed the presence of fluid on the right. Thoracentesis had been performed several times. Physical examination at the clinic disclosed signs of fluid in the right part of the thorax. This was confirmed by roentgenologic examination (Fig. 2). A large, firm, movable mass filled the suprapubic region of the abdomen. A fluid wave and shifting dullness were demonstrable. Thoracentesis was performed on the right. Surgical exploration was carried out, and a large fibroma of the left ovary, measuring 15 by 30 by 15 centimeters, was removed (Fig. 3). The tumor weighed 1,370 grams. A roentgenogram made 15 days postoperatively demonstrated a decrease in the amount of fluid in the thorax (Fig. 4). A roentgenogram made 15 months postoperatively showed that the fluid had disappeared completely (Fig. 5).

Fig. 4. Roentgenogram of the thorax of the patient in Case 7 made 8 days postoperatively showing a decrease in the amount of fluid on the right.

Fig. 5. Roentgenogram of the thorax of the patient in Case 7 made 15 months postoperatively showing complete disappearance of the fluid evident in Figure 2.

CASE 8. A 67 year old single woman entered the clinic on September 9 1944 complaining of abdominal enlargement of 6 months duration Roentgenologic examination of the thorax showed fluid about the right base. The abdomen was enlarged and a fluid wave and shifting dullness were demonstrated. A large pelvic tumor was noted. On abdominal exploration a large fibroma of the right ovary was removed. It measured 15 by 10 by 9 centimeters.

CASE 9. A 41 year old married woman entered the clinic on September 27 1944, complaining of marked increase in the size of her abdomen during the preceding 3 months. Roentgenologic examination of the thorax showed that fluid possibly was present in the right base. The abdomen was large and distended. Shifting dullness was present. A mass was felt in the right lower quadrant of the abdomen. Surgical exploration was carried out. Marked ascites was found to be present. A complex teratoma and dermoid cyst of the right ovary were removed together with the right fallopian tube, uterus and the left fallopian tube and ovary. The teratoma consisted for the most part of undifferentiated thyroid tissue.¹

CLINICAL FEATURES

Age of patients The average age of the 9 patients who had a pelvic tumor associated

with this paper was in the process of preparation, a tenth patient whose condition demonstrated the phenomena of Meigs' syndrome was seen. The following is an abstract of pertinent data.

A 71 year old white married woman entered the clinic on April 11, 1946, complaining of weakness and shortness of breath of 4 months duration. During the previous 4 years the patient had noted some degree of dyspnea and a slight increase in the size of her abdomen. On February 15 1946 her local physician had discovered fluid in the right side of the thorax and since that date thoracentesis had been performed 9 times. She had lost 12 pounds (4.5 kgm.) since February 1946. Physical examination revealed extensive pleural effusion on the right and a large pelvic tumor with questionable ascites. Roentgenologic examination of the thorax showed pleural effusion on the right side, with fluid extending up to the level of the third rib, anteriorly. On April 7 1946, thoracentesis was performed on the right and 3,450 cubic centimeters of pale, amber-colored clear fluid was removed. The specific gravity of the fluid was 1.07. A cell count revealed no cells. Results of culture were negative. The protein count was 2.7 grams per 100 cubic centimeters of pleural fluid.

On April 8 1946, 2 cubic centimeters of clear ascitic fluid was removed from the abdomen and cubic centimeters of sterile India ink was injected into the peritoneal cavity. Two days later thoracentesis was again performed on the right and 2,000 cubic centimeters of smoky fluid containing India ink was removed, thus demonstrating the passage of fluid from the peritoneal cavity into the right pleural cavity. After thoracentesis, an abdominal exploratory operation was performed. A moderate amount of ascitic fluid was present. A large tumor about 10 centimeters in diameter was removed from the left ovary. A small fibrous-appearing tumor of the right ovary also was excised. Appendectomy was performed.

Pathologic examination of the tissues removed disclosed an edematous, degenerating, cystic fibroma of the left ovary measuring 11 by 7 by 7 centimeters. The tumor was attached to a small pedicle which apparently had undergone several twists. There was a fibroma of the right ovary 5 millimeters in diameter. The appendix showed chronic inflammation. Fluid from both the abdomen and thorax contained many pigment laden cells. Study of the peritoneal coat of the appendix demonstrated similar phagocytosis by the lining mantle of mesothelium.

with ascites and hydrothorax was 48 years the age of the youngest was 36 and the age of the oldest was 67 years. Both of these patients had ovarian fibromas.

Marriage and pregnancy Six of the patients were married and 3 were single. Of the married patients, 4 had given birth to 1 child or more, and 2 had no children. It was thus apparent that the parity of the patient had no relationship to the development of the syndrome.

Complaints The most common symptom of which the patients complained at admission was enlargement of the abdomen. Some of the patients also noted the presence of a tumor mass. Abdominal bloating and shortness of breath were the next most common symptoms, and they occurred with about equal frequency. Pain was comparatively infrequent usually arose from the lower part of the abdomen and was mild. Some patients had a cough in association with dyspnea. The cough usually was nonproductive. The duration of symptoms had varied from months to 5 years. The menstrual function of 4 patients was essentially normal. 3 patients had undergone the menopause. 1 had menorrhagia and 1 had metrorrhagia.

Physical examination In nearly every case the triad pelvic tumor ascites and hydrothorax was demonstrable by physical examination and roentgenograms or by roentgenograms alone. Ascites was noted clinically in all the cases. In several cases a pelvic tumor was not noted prior to operation and in several other cases the presence of pleural effusion had not been suspected prior to the routine roentgenologic examination of the thorax.

Laboratory examination Results of laboratory examination did not contribute any pertinent positive diagnostic information.

Diagnosis The usual common causes for ascites presented a problem in differential diagnosis to the examiners of this group of patients. Cardiac disease renal affections cirrhosis of the liver tuberculosis, and malignant peritonitis were some of the conditions which had to be distinguished from the true underlying pathologic process. Malignant neoplasm of the ovary with ascites and

Fig. 2. Preoperative roentgenogram of the thorax of the patient in Case 7. The entire right lung apex is obscured by fluid.

Fig. 3. Large ovarian fibroma removed from the patient in Case 7, showing a fibrous and edematous cut surface, with a large central cystic and necrotic region.

in the uterus had been discovered 4 months previously. Physical examination of the thorax revealed nothing abnormal but roentgenologic examination disclosed fluid in the right base. Abdominopelvic examination showed a large multilocular mass. Multiple uterine fibromyomas with diffuse pelvic inflammatory disease were found at exploration. A moderate amount of free fluid was found in the abdomen. Total abdominal hysterectomy bilateral salpingo-oophorectomy and appendectomy were done.

CASE 7. A 43 year old married woman entered the clinic on November 21, 1943 complaining of dyspnea of 18 months' duration. Roentgenologic

examination of the thorax in April, 1943 had revealed the presence of fluid on the right. Thoracocentesis had been performed several times. Physical examination at the clinic disclosed signs of fluid in the right part of the thorax. This was confirmed by roentgenologic examination (Fig. 2). A large, firm, movable mass filled the suprapubic region of the abdomen. A fluid wave and shifting dullness were demonstrable. Thoracocentesis was performed on the right. Surgical exploration was carried out, and a large fibroma of the left ovary, measuring 15 by 30 by 15 centimeters, was removed (Fig. 3). The tumor weighed 1,370 grams. A roentgenogram made 18 days postoperatively demonstrated a decrease in the amount of fluid in the thorax (Fig. 4). A roentgenogram made 15 months postoperatively showed that the fluid had disappeared completely (Fig. 5).

Fig. 4. Roentgenogram of the thorax of the patient in Case 7 made 8 days postoperatively showing decrease in the amount of fluid on the right.

Fig. 5. Roentgenogram of the thorax of the patient in Case 7 made 15 months postoperatively showing complete disappearance of the fluid evident in Figure 2.

CASE 8 A 67 year old single woman entered the clinic on September 9, 1944 complaining of abdominal enlargement of 6 months duration. Roentgenologic examination of the thorax showed fluid about the right base. The abdomen was enlarged and a fluid wave and shifting dullness were demonstrated. A large pelvic tumor was noted. On abdominal exploration a large fibroma of the right ovary was removed. It measured 15 by 10 by 9 centimeters.

CASE 9. A 41 year old married woman entered the clinic on September 27, 1944, complaining of marked increase in the size of her abdomen during the preceding 2 months. Roentgenologic examination of the thorax showed that fluid possibly was present in the right base. The abdomen was large and distended. Shifting dullness was present. A mass was felt in the right lower quadrant of the abdomen. Surgical exploration was carried out. Marked ascites was found to be present. A complex teratoma and dermoid cyst of the right ovary were removed together with the right fallopian tube, uterus and the left fallopian tube and ovary. The teratoma consisted for the most part, of undifferentiated thyroid tissue.¹

CLINICAL FEATURES

Age of patients. The average age of the 9 patients who had a pelvic tumor associated

While this paper was in the process of preparation, a tenth patient whose condition demonstrated the phenomena of Meigs' syndrome was seen. The following is an abstract of pertinent data.

A 71 year old white married woman entered the clinic on April 11, 1946, complaining of weakness and shortness of breath of 4 months duration. During the previous 4 years the patient had noted some degree of dyspnea and a slight increase in the size of her abdomen. A small fibrous-appearing tumor of the right ovary also was excised. Appendectomy was performed.

Pathologic examination of the tissues removed disclosed an edematous, degenerating, cystic fibroma of the left ovary measuring 10 by 7 by 7 centimeters. The tumor was attached to a small pedicle which apparently had undergone several twists. There was a fibroma of the right ovary 5 millimeters in diameter. The appendix showed chronic inflammation. Fluid from both the abdomen and thorax contained many pigment laden cells. St. dy of the peritoneal coat of the appendix demonstrated similar phagocytosis by the lining mantle of mesothelium.

with ascites and hydrothorax was 48 years the age of the youngest was 36 and the age of the oldest was 67 years. Both of these patients had ovarian fibromas.

Marriage and pregnancy. Six of the patients were married and 3 were single. Of the married patients, 4 had given birth to 1 child or more, and 2 had no children. It was thus apparent that the parity of the patient had no relationship to the development of the syndrome.

Complaints. The most common symptom of which the patients complained at admission was enlargement of the abdomen. Some of the patients also noted the presence of a tumor mass. Abdominal bloating and shortness of breath were the next most common symptoms, and they occurred with about equal frequency. Pain was comparatively infrequent usually arose from the lower part of the abdomen and was mild. Some patients had a cough in association with dyspnea. The cough usually was nonproductive. The duration of symptoms had varied from months to 5 years. The menstrual function of 4 patients was essentially normal. 3 patients had undergone the menopause. 1 had menorrhagia and 1 had metrorrhagia.

Physical examination. In nearly every case the trand pelvic tumor ascites and hydrothorax was demonstrable by physical examination and roentgenograms or by roentgenograms alone. Ascites was noted clinically in all the cases. In several cases a pelvic tumor was not noted prior to operation and in several other cases the presence of pleural effusion had not been suspected prior to the routine roentgenologic examination of the thorax.

Laboratory examination. Results of laboratory examination did not contribute any pertinent positive diagnostic information.

Diagnosis. The usual common causes for ascites presented a problem in differential diagnosis to the examiners of this group of patients. Cardiac disease renal affections cirrhosis of the liver tuberculosis, and 'malignant' peritonitis were some of the conditions which had to be distinguished from the true underlying pathologic process. Malignant neoplasm of the ovary with ascites and

pleural metastasis, was the condition most often mistaken for a benign pelvic tumor associated with ascites and hydrothorax.

It is of historic interest to note that in Case 1 of the series reported herein the late Dr W J Mayo in 1917 made the preoperative diagnosis of fibroid tumor of the ovary in a patient who had ascites and hydrothorax. At operation a large fibroma of the ovary was found. Since 1937 when Meigs syndrome was recognized as an entity only 2 patients who had fibroma of the ovary with ascites and hydrothorax have been seen at the Mayo Clinic. In both of these cases the preoperative diagnosis of Meigs syndrome was made.

PATHOLOGIC DATA

Types of tumors The lesions in the 9 cases reported herein consisted of 4 ovarian fibromas, 1 ovarian fibromyoma, 1 degenerating uterine fibromyoma, 1 fibromyoma of the uterus with pelvic inflammatory disease of the adnexae, 1 granulosa-cell tumor of the ovary and 1 complex teratoma of the ovary.

Side of involvement Five of the ovarian tumors were on the right side, 1 was on the left, and the location of 1 could not be determined on the basis of the data. Both the granulosa-cell tumor and the teratoma occurred on the right side. The 2 uterine fibromas were not localized as to side.

Size of tumor All the tumors in this series were large. The average diameter was 16 centimeters.

Color of tumor The ovarian fibromas were whitish or grayish white with a fine whorled appearance on cut section. The granulosa-cell tumor was grayish brown and was encapsulated.

Consistency All the tumors were of the solid variety. Of the 5 ovarian fibromas, 3 face cysts were present on the granulosa-cell of ovarian tumor in the series, and in 3 cases distention of the peripheral veins was present. In 3 of the cases adhesive tags were noted on the surface of the lesion.

Ascites and hydrothorax Abdominal ascites accompanied the hydrothorax in all of the cases. Usually the fluid was considerable. In

7 of the cases pleural effusion was located on the right side, in 1 it was confined to the left pleural space and in 1 it was bilateral. Performance of thoracentesis was necessary for 4 of the patients, 3 had undergone thoracentesis more than once. Abdominal paracentesis was performed for only 1 patient (Case 4), 13,000 cubic centimeters of clear straw-colored fluid being removed. At surgical exploration the amount of fluid varied from moderate to considerable amounts as much as 3 to 4 gallons being removed from 1 patient. The fluid usually was described as being clear or straw colored. Diagnostic tests made upon fluid removed from the abdomen and thorax in these cases were of value only negatively, namely in helping to rule out tuberculosis and malignant neoplasms.

Possible contributory factors to the occurrence of ascites may be mentioned in several of the individual cases. In the case of degenerating uterine fibromyoma (Case 4) the surgeon noted that a large fibroid tumor was incarcerated tightly in the pelvis, and thought that this might have accounted for the ascites. A similar situation was noted in 1 of the cases of fibroma of the ovary. In our case of pelvic inflammatory disease and of granulosa-cell tumor twists in the pedicle were noted and were thought to have contributed to the production of ascites. Ascites frequently is an accompaniment of ovarian tumors which contain large amounts of thyroid tissue, as has been pointed out by Masson and Mueller. As previously mentioned gross edema of the tumor or its pedicle or both was present in every case of ovarian tumor in the series.

Histopathologically moderate to marked intercellular edema was noted in every case of the series and it was particularly notable in the ovarian fibromas. In these there was marked separation of the tumor cells by the edema fluid often associated with this were dilated blood vessels. Otherwise the tumors exhibited no microscopic deviations from the picture seen in other similar tumors not associated with the syndrome under consideration.

END-RESULTS

All the patients made uneventful recoveries after surgical treatment and the end results

were uniformly excellent. There was no recurrence of either ascites or hydrothorax in any of the patients. The longest follow up period extended over 27 years.

COMMENT

The incidence of ovarian fibromas varies from 1 to 5 per cent of ovarian tumors according to different authors. Masson and one of us (Dockerty) found that 312 of such tumors accounted for 5 per cent of all ovarian tumors surgically removed at the Mayo Clinic. The fibroma is one of the most common of the solid ovarian tumors. The comparatively frequent occurrence of ascites in association with ovarian fibromas has been recognized for some time, but the frequency of this occurrence has been variously reported. Peterson in 82 cases collected from the literature plus 2 of his own found that the incidence was 40 per cent. Hoon noted that ascites was present in 25 per cent of 55 cases collected at the Mayo Clinic, and in a more recent report from the same institution Masson and one of us (Dockerty) found that ascites accompanied 36 per cent of 141 fibromas the diameters of which exceeded 6 centimeters. Meigs and Cass reported the incidence of ascites to be 13 per cent in 29 cases of fibromas from the Massachusetts General Hospital.

Rubin and associates in reviewing Miller's large collection of 2 748 ovarian tumors from various sources found that ascites accompanied 6 per cent of the benign tumors and 45 per cent of the malignant tumors. The same authors noted that ascites had occurred in 30 per cent of their series of 23 theca-cell tumors of the ovary. In both Peterson's and Rubin's series, the amount of ascitic fluid was not proportional to the size of the tumor.

Origin of ascites Since ascites generally is present in all forms of intraperitoneal carcinoma, the association of ascites with any pelvic tumor usually leads to the clinical impression that the tumor is malignant. In such cases the ascitic fluid is produced by chemical irritation of the peritoneum, which gives rise to a serous transudate and also to the secretion of malignant implants. The presence of the ascitic fluid in most of the cases of Meigs' syndrome, however, cannot be explained on the

basis of chemical irritation of the peritoneum. Such attempts at explanation have proved entirely unsatisfactory.

Rather a direct cause-and-effect relationship is involved because removal of the tumor stops the formation of the abdominal fluid. Some have attempted to explain the origin of the ascites on the basis of Selye's alarm reaction (21, 48). The latter reaction is the response of the organism to an irritant (in this case a pelvic tumor) with the production of a typical syndrome the symptoms of which are independent of the nature of the damaging agent, and represent a response to damage as such. Among the responses is the production of pleural and peritoneal transudates. Selye regarded this stage as the expression of general alarm on the part of the organism and termed it the 'general alarm reaction'. It might be compared to other general defense reactions such as inflammation or the formation of immune bodies. After repeated insults by the irritant the organism builds up resistance and normal function returns. But after a period of months of continued trauma the resistance disappears and there then appears a histamine toxicosis or anaphylactic shock, plus accumulations of peritoneal and pleural transudates.

The aforementioned hypothesis may be valid in certain experimental work, but it is not logical to explain Meigs' syndrome on the basis of such experimental observations. The pelvic tumor usually associated with ascites and hydrothorax is a fibroma of the ovary. That the mere presence of the ovarian fibroma in the peritoneal cavity is not a sufficient cause for the production of ascites is attested to by the fact that uterine myomas, despite their size similarity in structure and degenerative changes cause ascites very rarely although they are much more frequent in occurrence than are ovarian fibromas. Kelly and Cullen reported 5 such cases in which ascites undoubtedly had been caused by the presence of uterine myomatous tumors and in 1 case pleural effusion was present as well. Salmon reported a similar case and 1 case from the present series (Case 4) fits into this category.

Schenck and Fis offered an interesting hypothesis in explaining the production of

pleural effusion in such instances. They considered the presence of a pelvic tumor to be the initial factor the tumor by compressing the large abdominal lymphatic channels, retards the lymph flow through them. Schenck and Eis thought that when absorptive avenues through capillaries and lymph channels are abrogated such as occurs in toxic damage to endothelium increased permeability based on anaphylaxis and obstruction to the flow of lymph fluid becomes trapped in large serous cavities and a vicious cycle results in ascites and pleural effusion and if this cycle is allowed to continue, subcutaneous edema. In reality this explanation seems to be derived from Selye's alarm reaction plus the added factor of lymphatic obstruction by the compressing effect of the tumor. The fact that most of these tumors are large leads further credence to this theory.

As has been previously stated there is insufficient evidence to explain the ascites on the basis of lack of protein in the blood. The number of serum protein determinations that have been found to be normal in this condition is insufficient to rule out such a condition as a cause. The ascitic fluid found in cases of pelvic tumor associated with ascites and hydrothorax varies in quantity from small amounts to 8 or 10 liters. In most cases, the fluid is clear and straw colored and chemically appears to represent a transudate. In some instances it is blood tinged, and in such cases there is often evidence of recent twisting of the pedicle of the tumor.

One of the more recent and more nearly adequate explanations of the etiologic basis of the ascitic fluid is that offered by Masson and one of us (Dockerty) who in a combined clinical and pathologic search for the etiologic common denominator found the following facts to be pertinent. Edema of the tumor or its pedicle or both was present in 31 of 51 cases of ovarian fibroma in which ascites was associated. This incidence of edema was twice that observed in the group of tumors not associated with ascites. Central cystic degeneration with or without edema, frequently was noted in tumors of the ascitic group, but was rare in the group of cases in which no free peritoneal fluid was observed at the time

of operation. In 30 per cent of the cases in which there was ascites, adhesions, probably resulting from ancient twists of the pedicle of the tumor also were present. Pain was an important clinical feature in this latter group. Small fibromas contained within the true pelvis were not productive of ascites.

Histopathologically the aforementioned authors found that intercellular edema correlated more often than did gross edema and formation of cysts with the clinical production of ascites. Including the cases of edema with formation of cysts, separation of tumor cells by an excess of tissue fluid was observed in 70 of the 312 ovarian fibromas examined. Significant was the fact that of 51 tumors accompanied by ascites, 49 (96 per cent) exhibited edema, usually in marked degree. This was in contrast to an incidence of 10 per cent for edema in tumors not accompanied by ascites. In no instance was epithelium of a secretory type found on the surface of a fibroma where it might conceivably have given rise to ascites.

In connection with pathologic degeneration of the ovarian fibroma as a possible cause of ascites, Rubin and associates asked why ovarian fibromas produce ascites so commonly whereas uterine fibroids do so rarely even though both tumors have a similar parenchymatous histologic structure and undergo similar circulatory and degenerative changes. The explanation of Rubin and associates was found in the fact that uterine fibroids, are, as a rule covered by a dense fibromuscular capsule and invariably by a serosal layer whereas ovarian fibromas do not have such a capsule, and, like the normal ovary, have no peritoneal cover. Instead of a true serosa, ovarian fibromas are covered by a low single-layered, very vulnerable and easily permeable surface mantle which offers practically no resistance to the penetration of fluid from the ovarian tumor. A more likely explanation may be that, for purely anatomic reasons, the ovarian vessels are more vulnerable to compression by a tumor mass or to twists in the pedicle than are the uterine vessels.

Origin of hydrothorax. To attempt to explain the origin of ascites when it accompanies certain pelvic tumors, notably ovarian fi

bromas presents a difficult problem in itself but when there is added the concomitant occurrence of hydrothorax in some of these cases the problem becomes even more perplexing. It is well to reiterate the direct cause-and-effect relationship mentioned in connection with ascites. That is, the failure of fluid to reaccumulate in either thorax or abdomen after removal of the tumor suggests that the tumor was responsible for the effusion. It has been pointed out that pleural effusion which accompanies ascites occurs more frequently on the right side than on the left. Meigs and Cass thought that lack of drainage of the right portion of the thorax by the azygos vein might explain this phenomenon but later they did not believe this was an adequate explanation inasmuch as the effusion also was found in the left part of the thorax and bilaterally. Borg reported a case of Meigs' syndrome with bilateral fibroma of the ovaries in which the patient died without the benefit of surgical treatment. At necropsy the azygos vein was found to be very large—being twice as wide as the abdominal aorta. It is difficult to evaluate to what extent the azygos system of venous drainage was interfered with and just what role such interference might have played in the pathogenesis of the hydrothorax.

Lemon and Higgins and others (18, 19, 24, 26) have demonstrated experimentally the pathway by which lymphatic absorption of particulate matter proceeds through the diaphragm. They have shown that both surfaces of the diaphragm with the exception of the tendinous center are richly supplied with lymph vessels. Each half of the diaphragm forms its own separate area of lymphatic drainage and communicates but slightly with the other side. The lymphatic vessels on the right side are much larger and carry a greater proportion of the lymphatic flow than those on the left. Particulate matter is taken up diffusely on the subperitoneal surface of the diaphragm and passes between the mesothelial cells of the peritoneum into minute lymphatic vessels from these minute vessels it passes to the muscle bundles until it is deposited in the subpleural lymphatic network. This transfer is rapid; it requires only 3 to 5 minutes in the normal muscle and 30 to 90 minutes in a para-

lyzed diaphragm. There are five main routes of communication between the peritoneal and pleural cavities. The first is the sternal route which is the main channel and accounts for 80 per cent of the lymphatic drainage. It consists of three to four channels which course along the diaphragm between the intercostal muscles and proceed forward parallel to the thoracic artery and vein. The second route is the pulmonary route which extends to the nodes at the hilus of the lungs. The third is constituted by vessels which run to the thoracic duct. The fourth route consists of vessels which course over the dorsal surface of the diaphragm pierce it and empty into the lymph nodes in the region of the kidney. The fifth route is comprised by vessels that pass over the vault of the diaphragm pierce it anterior to the aortic opening then pass to the splenic mesentery and thence to the nodes in the region of the pancreas.

Lemon and his associates (25-27) have shown that fluids as well as particulate matter and bacteria are removed by the diaphragmatic lymphatic system in the transference from the subperitoneal to the subpleural lymph vessels and they have demonstrated that this is a one-way communication. Although particulate matter injected into the abdomen of an animal reached the diaphragmatic lymphatic vessels, particulate matter injected into the thorax did not reach the inside of the abdomen. The direction of flow thus follows the direction of the normal current toward the heart. This is dependent mainly on the normal muscular contraction of the diaphragm. Florey in his experimental work noted that an intra-abdominal pressure of 3 to 5 centimeters of water was caused by the respiratory movements of the diaphragm. Intrathoracic pressure was negative to an almost equal degree. The difference in pressure on the two sides determines the direction of flow of the lymph.

The aforementioned work has demonstrated the passage of particulate matter through the diaphragm in the experimental laboratory. Yet as Meigs and associates have pointed out whether or not the material would be found in pleural effusion was not proved but only suggested because the experimental animal has

no fluid in the thorax such as is present in pleural effusion.

Meigs and his co-workers deserve much credit for a fine clinical investigation of 2 patients who had Meigs' syndrome and who were operated on in 1941. These authors were able to examine the diaphragms of the 2 patients to collect fluids for analysis, and to demonstrate the passage of particulate matter from the abdominal fluid into the fluid in the thorax in all probability through the diaphragmatic lymphatic vessels.

Ritvo reported a case of Meigs' syndrome in which peritoneoscopy was performed before the patient was operated on and in which air was left in the peritoneal cavity in an effort to demonstrate any passageway if such existed for air from the abdomen into the thorax. Roentgenograms were made immediately; these did not demonstrate that air found its way into the pleural space. On the basis of Meigs and Ritvo's observations then it is unlikely that ascitic fluid reaches the pleural spaces by way of an opening through the diaphragm.

Rubin and his co-workers attempted to evaluate certain factors in the experimental production of Meigs' syndrome, and suggested several possibilities as to why ascitic fluid is not found in the pleura in every case of ascites. First, they wrote the fluid entering the pleural cavity is absorbed rapidly thus preventing accumulation of fluid in the pleural cavity. Second the passage of fluid through the diaphragm is slow so that the fluid is absorbed by the pleura with the same speed it takes to reach it. Third the diaphragmatic stomas are blocked or obliterated by debris or chronic inflammatory changes of the peritoneum. Fourth the high osmotic pressure of the colloidal ascitic fluid counteracts the transudation of water.

CONCLUSIONS

The association of ascites and hydrothorax with pelvic tumors was described in the older medical literature but remained comparatively unknown to most of the medical profession until Meigs' classical report in 1937. The greatest credit is due Meigs for recognizing this syndrome and pointing out its

clinical importance. A condition once thought to be an inoperable malignant process is now amenable to complete surgical cure. Meigs' syndrome originally was described as the coexistence of ascites and hydrothorax with benign fibroma of the ovary. Other pelvic tumors, however both benign and malignant, should be included in the syndrome because they are being reported in the literature with increasing frequency.

Nine cases of pelvic tumor associated with ascites and hydrothorax were found in the records of the Mayo Clinic. In a tenth case the patient was seen at this clinic after the present paper had been completed. The 9 cases included 5 ovarian fibromas, 1 degenerating uterine fibromyoma, 1 fibromyoma of the uterus with pelvic inflammatory disease of the adnexae, 1 granulosa-cell tumor of the ovary and 1 complex teratoma of the ovary. In the tenth case the lesions were ovarian fibromas. Pathologically all the tumors were of the solid variety and were large, averaging 16 centimeters in diameter. Gross edema of the tumor was noted in each of the 10 specimens. Microscopically intercellular edema was noted in each tumor. It would seem that this edema can be correlated with the clinical production of ascites in each case. A large solid tumor can readily produce partial venous obstruction, edema, and in turn ascites. Partial obstruction to the venous return also may result from twisting of a pedicle, inflammation, or adhesions. In 8 of the 10 cases, hydrothorax was situated on the right side. It was bilateral in 1 case and had occurred on the left side in 1 case. On the basis of the evidence reviewed it appears that the fluid in the thorax results from the passage of ascitic fluid through the diaphragmatic lymphatic vessels.

SURGICAL SUBSTITUTIONS FOR LOSSES OF THE EXTERNAL EAR

Simplified Local Flap Method of Reconstruction

JAMES BARRETT BROWN MD F.A.C.S. Colonel MC, A.U.S. St. Louis, Missouri
BRADFORD CANNON MD F.A.C.S. Major MC, A.U.S. Boston, Massachusetts
CARL LISCHER, MD F.A.C.S. Major MC, A.U.S. St. Louis, Missouri
W B DAVIS MD Major MC A.U.S. Baltimore, Maryland, and
ANDREW MOORE, MD Captain MC A.U.S. St. Louis, Missouri

LOSSES of the external ear are numerous and often complicate other serious defects so that plans for rapid and simple restoration are important without the use of massive distant flaps or great numbers of operations. The losses result mostly from burns gunshot wounds traffic accidents and freezing. Congenital absence and loss from neoplasms account for a relatively small but important number.

When enough surrounding scalp tissue is present a fundamental plan can be used of freshening whatever is left of the stump of the ear and implanting it carefully under a scalp flap behind and above the ear. When union is firm (2 to 3 weeks) an adequate piece of costal cartilage is put in under the scalp flap in the desired shape. In another 3 to 4 weeks, when there is no swelling the flap and cartilage are dissected free of the skull so as to leave soft tissue attached to the under surface of the cartilage and to the skull. This procedure requires accurate dissection. The resultant double raw surface is grafted with a single large thick split graft. Later adjustment may be necessary. If there is not adequate size or the patient requests it a small tubed flap from the immediate neck region can be added for the helix this however is seldom requested.

With this simple plan losses of the helix and pinna can be repaired in two operations and total reconstructions of both ears have been done in as little as three operations (Fig 1)

The patients in this series have been cared for in association with M. J. C. P. Scarborough, Captain Joseph Murray Major Byron West, Lieutenant Allan McDonald, Lieutenant Milton Edgerton, Major Sorenson, Lieutenant Jensen.

In making an ear skin in front and behind is needed with adequate support (or armature) in between. The scalp skin that was behind the ear is brought to the front surface of the ear cartilage (preserved or fresh) forms the support, and a free graft goes in behind. It is recognized that a completely normal total ear cannot be made. There is no tissue available to make it with if it could be done. Although fresh (or preserved) ear cartilage may be used, or chips of costal cartilage may be molded into the exact shape the skin available usually will not fit into the various recesses of the concha, triangular space and curves of the helix to bring these variations of the cartilage into prominence. For these reasons, the restorations are recognized as substitutions, and size general shape and direction are concentrated on in total restorations, but a general outline and prominence may at least fail to attract notice. Many friends and surgeons have talked to the patient in Figure 1 without noticing that both external ears have been totally reconstructed.

Prosthetic ears of latex or soft plastic are used according to patients wishes. They look like normal ears at a slight distance but have the trouble of falling off and require more care than most patients want to give. (Their routine use would be acceptable to most surgeons.) What the patient wants is the deciding point.

The cartilage is a problem in many ways of obtaining it, of shaping it and of having it persist as a firm support. In Figures 1 and 2 and 3 preserved costal cartilage has been used. A good supply is necessary and large

Fig. 1. Total loss from exposure to cold. Substitution done in 3 operations using local flap, single large piece of preserved cartilage and free split skin graft. Both ears in same condition repaired in same manner at same operations.

Fig. 2

pieces including the angle have to be on hand to supply a large single piece for a full ear. When large numbers of patients have to be cared for the preserved cartilage is almost entirely relied on and the opening of innumerable chests is avoided. The cartilage usually

can be obtained from the pathology department of a large hospital with proper selection of patients. It is thoroughly cleaned of all perichondrium and stored in merthiolate alcohol or other suitable chemical for use in the future.

Fig. 5. Total reconstruction of auricle. The stump of the cartilage is opened by removal of edge scar. A flap of ear rounding scalp tissue is raised and the stump is buried in under it. This is to go blood supply to the flap. When it is raised later

Fig. 6. After there is complete healing (3 weeks) an opening is made above and a complete tunnel made in the area. The curved portion of a costal cartilage is carefully carved to assimilate the normal contour and it is buried in the pocket.

Dand G. Parsons 3/27/46

Fig. 7. After the cartilage is firmly in place, the ear is cut loose from the scalp with careful dissection to leave viable soft tissue on both the cartilage and the skull. The double surface defect is covered with a thick split graft as shown.

Carving of the cartilage is done in the operating room with no special equipment other than knives and a board. It is put in place through an incision above into a pocket that is made with scissors. A good arm or strut is aimed down into the region of the crus of the helix to gain as much support as possible. Cartilage from other areas such as the knee and septum and from animals has been tried but for an active service using a large amount, a good source of fresh autopsy material is highly advisable (That some other foreign substance may prove satisfactory is hoped).

When the hairless skin around the ear is too limited or is scarred and glazy it may be necessary to do preliminary free grafting over the area or to cut away just what hair is in the way and graft this area. Then the ear will be made out of grafts in these areas the stages are necessarily slowed up and greater care is necessary in the dissection.

When there has been avulsion of all local tissue as in gunshot wounds or traffic accidents local flaps rather than free grafts may have to be supplied even to get started. Flap skin is thicker than the normal scalp in this

SURGERY GYNECOLOGY AND OBSTETRICS

FIG. 2. The steps of two stage restoration of helix without necessity of cartilage. The edge is opened, a scalp flap is prepared, the ear remnant is planted under it at first operation. At the second operation the ear is cut loose from the scalp picking up the flap that was behind the ear to make the new helix. The resultant raw defects are grafted with a thick split graft.

area and therefore makes a bulkier ear. The flap may be brought up from the chest or neck. Figure 3 shows one that has been brought up in stages that has cartilage in it.

Ears that are crumpled from chondritis are very troublesome because of folds and uneven surfaces. If there is marked deformity of the cartilage even though it is under good skin consideration should be given the procedure of removing the deformed cartilage first and starting with as smooth a surface as possible. Trying to dig these lumps of cartilage out later is not very successful.

Partial losses as of the helix and pinna may not seem of much importance in comparison with other widespread destruction of tissue but a thin scarred burned rim of the ear can be very uncomfortable for the patient. The repair of these defects is usually so simple and can be done so rapidly that there is little reason for not carrying out this partial reconstruction whenever requested.

The method is not routine for every patient as there may be local shifts of small loose flaps or forward dissections and replacements behind but the fundamental, as stated, is to open the edge prepare a direct flap and either plant the ear under it or swing the flap into place. If cartilage is necessary it is put in from the top usually at a second operation the ear is cut loose from the scalp and the defect is grafted at a subsequent operation. The patient in Figure 1 had total restoration in 3 operations with the use of cartilage. In the one in Figure 4 just the soft tissue without cartilage was used.

Sensation is usually slow in developing but little complaint is made. It is of course necessary to protect the patient against temperature extremes.

The use of composite free grafts from the opposite ear may be considered for small losses of the ear and for restoration of the helix in total reconstructions.

RECONSTRUCTION OF THE ESOPHAGUS BY A SKIN-LINED TUBE

THOMAS W STEVENSON M D New York New York

LACK of esophageal continuity may be the result of congenital defect, trauma (usually chemical) or neoplasm. Improvement in anesthesia, chemotherapy and thoracic surgical technique has made it possible to save the lives of many individuals. Advances are particularly noteworthy in the group of infants with congenital tracheo-esophageal fistula and in the carcinoma group. Survivors should be considered candidates for esophageal reconstruction.

Various practical considerations make it necessary to select cases carefully. Many infants are weak and sickly and often unfortunately have other anomalies. Stenosis of the esophagus by itself presents a particular difficulty, because of the extensive scarring especially at the upper end. This factor usually prevents deliverance of a patent upper portion of the esophagus to the skin surface of the neck. Carcinoma patients are usually older and always undernourished. One is always concerned about local recurrence or remote metastasis.

From the Department of Surgery, the Plastic Surgery Service, Presbyterian Hospital and College of Physicians and Surgeons, Columbia University, New York.

Even though life has been saved and nutrition improved these patients still present a miserable picture. A gastrostomy is necessary with all of its inconvenience, local irritation, leakage, and loss of gustatory satisfaction. In addition there is an upper esophageal fistula with copious salivary leakage, and if the leakage is prevented by stenosis at the cutaneous junction saliva and food collect in the pharynx, causing discomfort and interference with respiration. It was the problem of relieving such a stricture at the skin surface that first caused us to consider the feasibility of reuniting the upper esophageal stump with the stomach.

CASE 1: J. I., a Puerto Rican widow aged 70 years first attended the clinic in June, 1937 because of hoarseness of 5 years duration. A pedunculated fibroma of the hard palate and polyp of the vocal cords were removed. Blood count, urine and stool examinations, Wassermann chest x ray films and gastrointestinal series were normal including the esophagus. On January 5, 1938 esophagoscopy was done to remove a piece of chicken bone lodged high on the anterior wall. In February 1941 she first noted pain in the chest and had difficulty swallowing anything but liquids. She returned to the clinic on April 21, 1941. Her health had been good since her

SURGERY GYNCOLOGY AND OBSTETRICS

Fig. 3. Front and side views, Case November 9, 1941

last admission. Fluoroscopy showed a 4 centimeter symmetrical constriction in the middle of the esophagus. A biopsy specimen was taken from a mass arising from the posterior wall 27 centimeters from the upper gum. This tissue showed squamous carcinoma. Chest x ray pictures were normal. On May 20, 1941 resection of the esophagus was done through the right 6th intercostal space by Dr. Allen O. Whipple and Dr. Richmond L. Moore. The lower esophageal

stump was inverted and the upper end brought out through the right supraclavicular fossa and sutured to the skin of the chest. A gastrostomy was done. Microscopically the tumor was poorly differentiated and involved muscularis. It measured 4.3 by 2.4 centimeters. The postoperative course was exceedingly smooth. Temperature was not elevated above 100.2 degrees. Sutures were removed on the 8th day. The patient was walking on the 9th day and was discharged from the hospital on the 18th day.

By August 15, 1941 the upper esophagus opening was entirely closed off despite attempts to keep it open. This segment remained distended and the patient was uncomfortable (Fig. 2). On September 2, 1941 the esophageal fistula was re-established. Unfortunately this fistula gradually became constricted. It was evident that a wide stoma was needed for the patient's comfort and was an essential step in any reconstruction. On December 16, 1941 the esophageal stump was freed and opened upward 2.5 centimeters, after which the skin and mucous membrane were sutured with interrupted No. 00000 plain cat gut. Primary union was obtained.

April 14, 1942 a skin lined tube, 13 centimeters in diameter was formed from the right infraclavicular region to the xiphoid. The patient was sent home on the 22nd day with the tube healed, but open at both ends. A strip of zeroform gauze was replaced in the tube at intervals of 2 to 3 days. The patient continued to gain weight and there was no irritation of the skin within the tube.

August 6, 1942 the lower part of the skin tube was extended down over the xiphoid and anastomosed to the anterior wall of the stomach. A 4 millimeter white nodule on the peritoneal surface of the stomach proved to be a leiomyoma. The patient's recovery was smooth. Her highest temperature was 100.0 degrees F. The wound healed primarily and sutures were removed on the 7th day. On the 13th day a glass connecting tube was used to link the upper end of the skin tube with the esophageal opening (a distance of 5 cm.) and the patient was allowed to drink a glass of water. The passage was free. The patient noted a sensation of coldness. Checked

Fig. 4. Case above anastomosis low. Not V-shaped junction with gastric mucosa.

Fig 5 Case 2 April 21 1942

Fig 6 Case 2 May 1 1942

Fig 7 Case 2 November 25 1942

Fig 8 Case 2 March 8, 1943

fluoroscopically the lumen of the skin tube appeared larger than that of a normal esophagus. There was occasional pyloric obstruction due to the mushroom gastrostomy tube and this caused regurgitation of strongly acid stomach content. It was noted that this regurgitated material irritated the exposed skin but not the skin lining the tube. Under local novocain anesthesia the skin tube was continued upward and joined to the esophagus. Healing was uncomplicated and 10 days later the patient was allowed to eat and swallow. Food passed freely down the tube. The gastrostomy tube was withdrawn and the stoma promptly healed. The patient began to regain strength and weight.

September 2 1942 17 months after esophagegostomy the patient developed pneumonitis with signs of consolidation at the left base and a temperature of 103 degrees F. She was flushed and coughing. A week later there was effusion in the left chest and mediastinal shift to the left indicating atelectasis. After aspiration of cloudy yellow fluid showing negative cultures and no tumor cells, x ray examination showed a wide mediastinal shadow which continued to enlarge and the patient became more cachectic. She died March 19, 1943. Autopsy showed carcinoma in the tracheobronchial lymph nodes, with extension to the posterior mediastinum and occlusion of the left main bronchus. The skin

Fig. 9. Front and right side views, Case 3. January 10, 1946

lining of the tube was smooth and clear. Scarring was not noticeable and there was no evidence of ulceration anywhere. The tube consisted of skin averaging 10 centimeters in circumference with no evidence of surrounding scar. A scarcely distinguishable suture line ran down the tube anteriorly. The juncture of the skin-lined tube with the stomach showed no scarring or ulceration, and the epidermis showed an abrupt transition to the normal gastric mucosa. The anterior wall of the stomach was adherent only at the site of anastomosis and at the obliterated gastrotomy.

Case 2. W. R., a 61 year old man complained of dysphagia for 3 months before his admission on November 19, 1941. He had lost 40 pounds in weight, and had had trouble swallowing fluids. Chest x ray pictures were normal except for calcified bronchial nodes. Barrum studies showed esophageal obstruction just below the arch of the aorta.

Esophagoscopy showed a tumor 33 centimeters from the upper teeth. Biopsy proved squamous carcinoma. Blood count normal erythrocyte sedimentation reaction 8 millimeters Wassermann negative weight 150 pounds. Histamine test showed no free hydrochloric acid total acid 9 after 40 minutes. December 19, 1941 esophagectomy was performed by Dr. Allen O. Whipple assisted by Dr. Richmond L. Moore. A right transthoracic approach through the 7th intercostal space was used. The pleura was found adherent and so was the esophagus in the region of the calcified nodes. It was necessary to excise the left vagus nerve with the mass. The upper esophageal stump was brought out just to the right of the suprasternal notch and a gastrostomy was made. The portion of the esophagus examined pathologically was 9 centimeters long and had a co-

Fig. 14. Exposure of stomach and V incision. Inset shows tube sutured to stomach.

Fig. 16. Elliptical incision has been made to join esophagus and skin tube. Insets show methods of closure.

stricting area of carcinoma 2.5 centimeters long. There was muscle invasion and mitosis averaged two per high powered field. The mucous membrane was much more extensively involved than was grossly recognizable. The postoperative course was stormy for 3 days because of bilateral pneumonitis. Temperature mounted to 105 degrees F. but settled to normal by the 7th day. The wounds healed well and the patient was discharged on gastrostomy feedings, on January 19, 1942, weighing 135 pounds. Upon readmission on April 20, 1942, the esophageal stoma was closed by a dense scar. This scar was excised and the stoma was enlarged (Figs. 5 and 6).

September 3, 1942, there was no constriction so a cutaneous tube 9 centimeters in diameter was formed from the sternal notch to the xiphoid. This was followed by union of the lower end to the anterior wall of the stomach (Figs. 7 and 8).

December 1, 1942, wound healing was uncomplicated and sutures were removed on the 9th day. Patient was discharged home on the 18th day.

March 9, 1943, the skin tube and esophagus were united without complication. The patient started

swallowing water on the 6th day, and soft diet was started on the 10th day. He has had no obstruction and has required no treatment. He became interested in having his teeth repaired. In order to do some chewing again, and resumed his work as a sheet metal worker in a war plant. His weight has been maintained at 150 pounds.

January 11, 1946, he was in good condition. His only untoward sensation is a strong perception of heat or cold on ingested food and fluids, and in the morning an itching sensation which he relieves with a cup of strong coffee (Fig. 9).

OPERATIVE TECHNIQUE

Stage 1. Formation of subcutaneous skin lined tube. Two parallel incisions are made from just below the esophageal stoma to the xiphoid. In the first case these were 12 centimeters apart, and in the second 9 centimeters. Eight centimeters may be enough. Incisions

SURGICAL GYNECOLOGY AND OBSTETRICS

were made to include the deep fascia and the lateral margins were widely undermined about 10 centimeters. The medial margins are freed about one third leaving the central third attached down the center (Figs. 10 and 11). The central layer is then rolled up skin surface in and sutures with two layers of interrupted No. 000 chromic catgut. The inner layer is tied with the knot inside the lumen and the outer layer in the fascia. The undermined lateral flaps are then closed over the chromic gut sutures being used in the fascia and interrupted dermal in the skin. A roll of this strip of gauze is passed down the tube. A fresh piece may be tied to the old one and pulled through as the old one is removed.

Stage 2. Anastomosis to stomach (Figs. 12, 13, 14 and 15). The tube is extended by continuing the two parallel cuts down almost to the gastrostomy which is carefully draped out of the operative field. The lowest 3 centimeters of the tube is left open. The anterior wall of the stomach is exposed through the left rectus and on inverted λ incision is made into the stomach. Each branch of the λ is 4 centimeters long. The skin of the tube is then sutured to the gastric mucosa with interrupted No. 000 chromic gut reinforced by a second layer of similar sutures between the fascio of the tube and the gastric serosa and muscularis. The linea alba needs a small vertical incision

to the xiphoid to insure against angulation of the tube. Then the wound is closed and the undermined skin is approximated. At this stage the gastrostomy needs to be kept open on bottle drainage most of the time because gastric content regurgitates freely up the tube and will excoriate the skin of the chest strangely enough however the skin of the closed tube can be seen to remain clear. Perhaps drying or oxidation is needed to activate the irritative process.

Stage 3. Junction of esophagus and skin tube (Fig. 16).

An elliptical incision is made vertically including the upper end of the original parallel cuts. The skin tube is then closed up to the esophageal stoma and the upper end of an ellipse turned down in the manner of an envelope flap to close the upper angle of the wound. The undermined skin margins are then closed. Liquid feedings in small amounts may be started as soon as the skin is healed.

SUMMARY

Loss of esophageal continuity may result from congenital defect, trauma or neoplasm. Improving surgical technique permits survival of an increasing number of patients, and this leads to consideration of a means of reconstruction. Two cases are presented with a description of the method used to unite the upper esophageal segment to the stomach by means of a skin lined tube.

SOME OBSERVATIONS ON WOUND HEALING

A Clinical Study with a Note on Topical Chemotherapy and Secondary Closure

JACK MATTHEWS FARRIS MD F.A.C.S. Los Angeles, California, and
THOMAS B JONES MD Rochester New York

THIS report is concerned with the management of wounds in a general hospital based in the United Kingdom and actively engaged in the treatment of wounded evacuated from the continent. Shortly after D Day it was necessary to outline a plan whereby a large number of wounds could be treated definitively. Where as everyone was well versed in the emergency treatment of wounds there was less agreement and precedent as to the definitive treatment. There were those who strongly advocated that all extensive soft tissue wounds with and without fractures be treated according to the principles popularized by Orr and Trueta while others postulated that in certain instances secondary closure and grafting might be utilized in the definitive treatment of open wounds after varying lengths of time. There was little agreement as to the rôle of local and systemic chemotherapeutic agents. Much information had been disseminated concerning arbitrary time intervals after which débridement and closure might be hazardous or inadvisable. Therefore it seemed that an excellent opportunity was at hand to make some observations upon the factors involved in wound healing.

Methods of study Approximately 6 000 patients were admitted to the surgical service in the 6 months after D Day. Between 2 000 and 2 500 wounds were secondarily closed. This is a report on approximately 725 that were treated on the general surgery section. The results have been carefully tabulated and provide the basis for this report.

The following plan was adopted. It was decided to make an earnest effort to close every wound either by secondary suture and/or graft as soon as it was reasonably certain that the

wound was not the site of active virulent infection. The closure of the wound was made the primary objective and the underlying fracture nerve injury foreign body tendon injuries or muscle defect when present were a secondary consideration. This policy was predicated on the premise that the best dressing for any wound is skin and the sooner it is applied the better is the ultimate prognosis of the associated injury.

Time interval All wounds were closed as soon as possible. Some of the wounds were closed within 3 or 4 days and many were closed during the first week. The majority were sutured or grafted between 7 and 14 days. It was believed that if the patient had not developed clinical evidence of local or systemic infection within 48 to 72 hours after the emergency treatment had been carried out there was little reason to continue open treatment of the wound in the anticipation of infection that did not exist. It soon became apparent that the earlier the wounds were closed the better were the results.

Early management after reception All wounds were dressed as soon as possible after admission. Vaseline packs were removed. Many of the large wounds had been enclosed in plaster casts often with admonitions against their removal. These were likewise promptly removed. A simple wet saline dressing was applied to all wounds in order to remove the caked sulfacryl crystals, vaseline exudate and old blood. It was remarkable to see the striking improvement in the appearance of these wounds after 24 to 48 hours. All medication (sulfadiazine and penicillin) was stopped after admission and subsequently given only in those cases in which there were systemic signs of infection. In one group of 100 patients it was necessary to give chemotherapy in only 2 instances when

Fig. 1. Wound of buttock, 7 days after injury. a, Large defect with divided gluteal muscles. There is minimum granulation tissue and this type of wound may be closed

without reëdification. b, Illustrates wound 7 days after closure with through-and-through mattress sutures of black silk. c, Wound at 24 days.

these indications were followed. The simple saline dressings were changed frequently in order to utilize the absorptive and capillary action of the gauze. Each time the gauze was removed and reapplied gross foreign matter was mechanically removed from the wound. Maximum benefit from the wet dressings was usually obtained in 2 or 3 days. As soon as it was felt that the wound was reasonably free of all gross particulate and organic matter closure of graft was done.

Technique of closure. The skin was carefully prepared with soap alcohol ether and a mercurial antiseptic. The wound was protected during this procedure with sterile gauze. The local anesthetic, when used was introduced circumferentially into the normal skin and was not put directly into the wound. Early wounds (less than 7 days old) were simply sutured together with little undercutting redëbriment seldom being necessary. These wounds did not have granulation tissue, were still mobile, and gave some of our very best results. Black silk sutures were used and only in exceptional instances were buried sutures used. When there was difficulty in obliterating dead space a large pressure dressing was put over the wound. Drains were practically never used. When large muscle groups had been interrupted it was often possible to approximate them by the use of figure-of-eight

black silk sutures which traversed the skin and were subsequently removed.

Older wounds (10 days and longer) were handled in a different manner. Simple closure over granulation tissue and its fibrous base invariably gives an unsatisfactory result. The wound by this time has lost a great deal of its mobility and closure of even minor defects is difficult without rather extensive undercutting of the wound edges. Therefore small granulating wounds whenever possible were completely excised in the same manner that one would excise a nevus or skin carcinoma. An elliptical incision was made in the normal skin about the wound and the granulating area with its base removed by sharp dissection so that the wound then possessed the appearance of a fresh one. Meticulous hemostasis was observed and the wound accurately closed without drainage. This operation of secondary débridement is of prime importance when dealing with granulating wounds. Wounds have healed exceptionally well when closed in this manner and rather unsatisfactorily when simple closure was attempted without excision of the granulation tissue and fibrous base.

Large skin defects oftentimes made closure impossible. These were closed by a combination of partial suture and split thickness graft. Secondary débridement operations were consistently carried out, and the skin edges were

Fig. 2. Soft tissue wound of elbow 3 days after injury. 3 days after debridement. a, Appearance of the wound after

24 hours of saline dressings. b, On 9th postoperative day simulates healing seen in clean operative wounds.

mobilized and sutured from the periphery in ward to render the defect as small as possible. A thin split thickness graft was then immediately sutured into the remaining defect over any exposed muscle, fascia, bone, tendon or nerves. On the thighs and legs some of these defects were enormous and the areas grafted in some instances extended from the buttocks to the knee. A successful take is almost invariably obtained when the graft is placed over these redbreided wounds, and in our experience the results are far superior to those obtained when grafts are placed over granulating surfaces.

Oral sulfadiazine (6 gm per day) was begun on the day before operation and continued for 4 or 5 days after operation to protect against an occasional spreading cellulitis. From the beginning we made a hard and fast rule that chemotherapeutic agents would not be used locally in the wound. Penicillin was employed neither systemically nor topically. We felt that if we were properly to evaluate the results it was of prime importance for all personnel to adhere rigidly to a well standardized procedure. It was originally planned to operate upon 50 patients with this technique for purposes of establishing a control. We were already convinced that chemotherapeutic agents used locally were of little value when the wound was ready for closure, and it was felt that in some instances the presence of these agents was even harmful and a deterrent to wound healing. From the beginning the results were out of all proportion to our anticipa-

tions and this policy was therefore followed in 600 consecutive cases. In an additional 125 cases a mixture of penicillin and sulfanilamide was dusted into the wound at the time of closure.

On the other hand on some of the other sections of the surgical service, notably orthopedics various types of topically applied agents were used freely. Some of the wounds were irrigated postoperatively with penicillin through tubes introduced into the wounds at the time of closure. Others had sulfanilamide alone and some were dusted with a mixture of sulfanilamide and penicillin. These wounds were followed closely; the results did not offer any convincing evidence that the local application of these chemotherapeutic agents offers any advantages, and the practice was eventually discontinued.

Foreign bodies. Insofar as possible foreign bodies were made a secondary consideration and wounds were frequently closed over tiny bits of shrapnel in inaccessible depths of the wound with no apparent interference in healing. After the wound was healed and if the foreign body was responsible for any symptoms, it was removed at a clean operation. This undertaking was thought to be preferable to one which would allow extensive dissections in a contaminated wound. Large foreign bodies however when they carry in segments of clothing must be removed. The cultures from these retained pieces of clothing frequently yield *Clostridium welchii* when there is no clinical evidence of gas bacillus infection.

SURGERY GYNECOLOGY AND OBSTETRICS

by undercutting and mobilization of skin margins; all granulation has been excised. c. A large split thickness graft was applied immediately as dressing for the remaining defect. d. Appearance of wound 8 days after operation. There is a complete take of the graft.

Foreign bodies 1 centimeter or over in diameter almost invariably have to be removed because of the cloth which has been carried in arbitrary categories. Group I included those that healed primarily without drainage. They usually required little or no dressing after 7 days and simulated the healing of clean operative wounds. Group II included those which exhibited wet healing. In this group there was usually some reaction about the sutures and frequently serosanguineous drainage. However the Group II wounds were well healed in 14 to 16 days and did not require any further definitive treatment and were considered to give just as satisfactory an end result as those in Group I. Groups I and II comprise the satisfactory group. Group III included those closures considered unsatisfactory because at

the end of 2 weeks they were not healed and frequently required additional surgical procedures, such as grafting, suture or strapping, to obtain final epithelialization of the wound.

In 600 patients who did not receive topical chemotherapy primary healing (Group I) was obtained in 67 per cent of all wounds closed. Wet healing (Group II) was obtained in 29.3 per cent. Unsatisfactory results (Group III) were obtained in 3.7 per cent of the cases. With this technique of wound closure 96 per cent of the cases (Group I and II) can be placed in the satisfactory group.

In 125 patients with dusted penicillin and sulfanilamide there was no significant difference in the total of satisfactory results (95.6 per cent). However there was an increased incidence in the "wet healing" group (35.6 per cent) and a somewhat lower per

c

centage in Group I (60 per cent). Unsatisfactory results occurred in 4.4 per cent of the cases.

When first confronted with several hundred large contaminated wounds of the buttocks, arms, legs and trunk it is not without some apprehension that one undertakes closure. It can be candidly stated however that in only a few instances throughout the entire series were signs of systemic infection observed following secondary suture. The most amazing defects could frequently be drawn together

with considerable tension and primary healing would still occur.

CASE REPORTS

CASE I. *Extensive wound of the buttock.* This soldier was wounded June 14, 1944 by a high explosive shell. Thorough débridement was carried out in Normandy, France. The wound was initially dressed with vaseline gauze and local sulfanilamide. Penicillin was not given in any form. He was given an indeterminate amount of sulfadiazine orally. He was admitted to the hospital June 20, 1944. Vaseline packs were removed and wet saline dressings applied on the 20th and 21st of June. The soldier was then

SURGERY GYNECOLOGY AND OBSTETRICS

Fig. 5. Compound fracture of the humerus. a, Ten days after injury. b, After re-debridement and closure. c, X-ray films. d, Two weeks after suture.

taken to the operating room and the wound closed under local anesthesia (1 week after injury). The wound was 5 or 6 inches in depth and the gluteal muscles were completely divided. Closure was accomplished with deep through-and-through silk sutures which included the margins of the divided muscle. No local chemotherapeutic agent was placed in the wound. The wound was closed under considerable tension as can be seen from the illustration (Fig. 1a) and the suture line was reinforced with strips of adhesive. A large pressure dressing was applied. Figure 1b shows the result at 1 week. No medication was given during the postoperative period except oral sulfadiazine for 5 days. At the end of 2 weeks the patient was up and about and the wound was completely dry and perfectly healed.

CASE 2. Extensive wound of the elbow. This soldier sustained a penetrating wound of the forearm near the elbow from a machine gun bullet on June 23, 1944. Débridement was not done until the following day at which time the wound was packed with vasoline gauze and sulfanilamide powder. He did not receive penicillin in any form. He was admitted on June 25, 1944. The vaseline pack was removed, wet dressings were applied for 24 hours and closure was done on June 26, 1944 (2 days after original dé-

bridement). No local chemotherapy was given. Sulfadiazine was given orally on the day preceding operation and for 4 days after operation. Complete primary healing was obtained. Physical therapy began 14 days after operation.¹

CASE 3. Abrasive wound of posterior aspect of thigh. This soldier was wounded on July 25, 1944 by an aerial bomb. There was extensive hemorrhage and shock, and débridement was not done until 48 hours following injury. He was evacuated to the United Kingdom and arrived in Oxford August 3, 1944 (5 days after primary débridement). He was in a plaster of paris hip spica and his field medical record contained the following note: "Recommend Cast not to be removed for a minimum period of 8 weeks because of massive tissue loss. Femoral artery femur and sciatic nerve exposed at time of operation for a distance of 6 inches." There was a nauseating odor as much drainage through the cast, and it was therefore promptly removed. The wound involved the

Gluteal region is almost invariably observed in wounds which are closed with few days of the primary débridement. Most of the complications in wound healing after secondary closure were observed in those wounds in the wound at the original operation and after 2 or 3 days, if necessary, drawing up the wound to be closed, the wound can be closed by simply drawing up the scarred (delayed primary suture).

entire thigh and was swathed in vaseline gauze. There was much purulent exudate in spite of the fact that he had received large doses of penicillin both at the field hospital in France (initial intravenous dose of 100,000 units) and during his transport to the United Kingdom.

A large simple saline dressing was applied and changed frequently during a period of 4 days, and on August 7 1944 he was taken to the operating room and a partial closure accomplished by mobilization of the skin margins (Fig. 3h). Granulations were just beginning to appear and they were removed from the muscle surfaces. The femoral vessels were exposed for a distance of 5 or 6 inches in the depth of the wound and the femur was covered only with a thin fascial layer. A single sheet of split thickness skin was taken from the opposite thigh with a free hand knife and sutured into place in the remaining defect (Fig. 3c). A large pressure dressing was applied. Figure 3d illustrated the appearance of the wound at the first dressing with a complete take of the graft. Physical therapy was begun in about 10 days and the patient was out of bed on the 24 day with the wound healed. Penicillin was not used. Nothing was put into the wound topically and the only medication was sulfadiazine orally.¹

CASE 4. Severe compound fracture of the femur. This soldier sustained multiple shrapnel wounds of the right thigh and abdomen and a compound comminuted fracture of the femoral shaft, also an intracapsular fracture of the neck of the femur on June 16 1944 in Normandy. A partial débridement was done about 4 hours later. Eviscerated loops of bowel were replaced within the abdomen, a portion of omentum resected and the abdominal wound closed. In the following 48 hours he received 5 units of plasma, 20,000 units of penicillin every 4 hours, two transfusions of whole blood and sulfadiazine topically and systemically. He was admitted to our general hospital 4 days after injury in very poor condition: temperature 101, pulse 120, hemoglobin 45, red blood count 1.9 million and white blood count 28,000. He was in a hip spica which was soaked with blood. He was given several blood transfusions in the following 48 hours and then taken to the operating room where the cast was bivalved. Figure 4 illustrates the condition of the wound June 22 1944, (6 days after the original injury) and it can be noted that there had been incomplete débridement. There was much necrotic tissue which was removed from the wound. A Kirschner wire was in-

serted into the tibial tuberosity for traction. A new double hip spica was applied. On July 6 the cast was bivalved and the wound treated extensively with saline dressings which were changed frequently in preparation for closure of the wound. On July 16 (1 month after wounding) the patient was taken to the operating room and the wounds were completely closed by secondary suture and split thickness graft (Figure 4b illustrates the appearance of the wound after wet saline dressings and secondary débridement and Figure 4d shows the wound immediately after secondary closure. Figure 4e shows the wound completely healed just before he was sent to the United States with a simple fracture of the femur in good position.

This case is an excellent example of how a severely wounded man with multiple injuries has gone through the various steps in the chain of evacuation to make a good recovery. It is our feeling that these compound fractures, no matter how severe, can be converted into simple fractures in many instances when good surgical principles are observed. On the other hand these extremely large wounds would take months to heal by secondary intention and when packed with gauze and kept open there is opportunity for infection of bone, secondary hemorrhage and disability from scar contracture. (This patient was treated in collaboration with Lieutenant Colonel Yancey, Chief of the Orthopedic Section and Major C. N. Mell, Assistant Chief of the Orthopedic Section.)¹

CASE 5. Compound fracture of the humerus. This soldier was wounded in the right shoulder by a high explosive shell on September 1 1944. There was severe hemorrhage and shock. He was treated in a field hospital 3½ hours later and débridement was done followed by the application of a shoulder spica. Penicillin was not used. He was given oral sulfadiazine in adequate amounts. He was admitted to this hospital 8 days after injury (September 9) and on September 11 he was taken to the operating room and the wound was closed without topical chemotherapy. Secondary débridement with complete revision of the wound was performed and he was given several transfusions for his anemia. (Figure 5 illustrates the appearance of the wound before and after closure and again 2 weeks later.) This is another example of how a very extensive compound fracture can be converted into a simple fracture by simple closure. This procedure is only possible because of the skillful débridement. He had a completely healed wound only 3 weeks after injury whereas the plaster treatment of such an open wound would result in purulent drainage and prolonged convalescence. There is also evidence to support the view that healing of bone is greatly enhanced when the wound is covered with skin. (This case was under the care of

¹This is a gratifying result and is much better than many weeks or months in a plaster cast. There likewise is complete restoration of function without limitation of motion by scar which is an inevitable sequel of prolonged healing by secondary intention. The presence or absence of fractures in the involved bone should not make the slightest difference in the basic principles involved in the healing of the wound. We consider early treated fractures of the femur with extensive soft tissue loss in the same manner. There is no question but that compound fractures of the femur with large vascular necks over a period of many weeks, invariably develop certain degree of bone infection whereas, if the overlying wounds are promptly closed, compound fractures, in the great majority of cases, is converted into simple fractures and infection avoided or minimized. This should prove to be one of the most significant contributions of the war, and differs radically from the original precepts popularized by Orr and Trause.

A survey of 100 consecutive compound fractures of the femur treated by secondary closure revealed that 9 per cent of them healed completely and were returned to the United States 6-9 days after hospitalization; 95 cases showed evidence of bony union. This series of cases will serve as the basis for subsequent report by Lieutenant Colonel Daniel L. Yancey, Chief of Orthopedic Section.

SURGERY GYNECOLOGY AND OBSTETRICS

Lieutenant Colonel D. L. Yancey Chief of Orthopedic Section and Major C. N. Mell Assistant Chief of Orthopedic Section.)

Analysis of results It has been surprising to observe that 96 per cent of so called contaminated wounds heal satisfactorily when closed by secondary suture. The policy of leaving traumatic wounds open after careful débridement and the rôle of systemic chemotherapy in the prevention of hemolytic infections no longer needs to be defended. However there is less agreement as to the management of these same wounds after they have once reached a general hospital where definitive treatment may be carried out. Medical curricula have rather universally included strict admonitions against the closure of contaminated wounds after some arbitrary time interval. Once this interval had expired it was thought necessary to keep these wounds open for an indefinite period of time in order to avoid infection which presumably would follow closure. The present experience shows that reasoning to be invalid. This is in contrast to experience reported in the last war. Several factors must be considered as a possible explanation for the excellent results that were obtained. In the beginning the excellence and promptness of emergency treatment rendered cannot be minimized. There are two outstanding features in connection with essential primary treatment—good surgical débridement and the transfusion of whole blood. Experience in this war has demonstrated that there is no substitute for the latter under battle conditions.

Penicillin The antibacterial potency of penicillin is well known. Many of the wounded had received penicillin both topically and systemically beginning at the forward area and continued through the echelons of evacuation. It was given on the LST's at regular intervals when the patients were brought across the channel as well as on air evacuation ambulances enroute to the United Kingdom. It is extremely difficult to accurately evaluate the effect that this prophylactic measure has had upon the subsequent absence of infection when these wounds were closed. We are inclined to minimize the effect that it has had upon the bacterial flora of the wound how

ever. For example some of our sickest patients had received penicillin in adequate amounts but arrived extremely septic because of retained clothing or necrotic tissue in the depths of a wound. It was invariably true that when débridement had been inadequate penicillin had little or no effect, and it was absolutely true that when débridement had been adequately done, it seemed to make little difference whether penicillin had been given or not. We admitted many patients over a period of several days. Their field medical records still carried a notation "penicillin treated and in the subsequent analysis of results, such cases gave an unreliable index of the efficacy of penicillin. Many patients had received none whatsoever and their subsequent course when definitive treatment was carried out, varied little or none from those in which large amounts of penicillin had been given. There were many patients who received a large initial intravenous dose at the time of débridement in France but did not receive a single dose thereafter. Their records are still classified as "penicillin treated and are misleading in this respect. It was rare to encounter a patient who had received therapeutic doses of penicillin at regular intervals and one must be extremely critical when evaluating the rôle that this drug played. Our cases did not receive penicillin either preoperatively or postoperatively except for definite indications. Wherever possible efforts were then made to identify the organism and its sensitivity.

A nearby general hospital on the other hand has used penicillin extensively as a prophylactic measure. During the month of July 1944, this neighboring hospital used 2,208,000 units, while in our work during the same period we used 9,500,000 units. In other words, in treating approximately the same number of patients with the same type of wounds, the neighboring hospital used 200 to 250 times the amount of penicillin that was used in our hospital. A few cases on the orthopedic service with compound fractures received penicillin irrigations to the open wounds. This practice was discontinued because there was little difference observed when these wounds were

compared with others that were treated with ordinary wet dressings.

Penicillin remains extremely valuable in the armamentarium of the war surgeon where definite indications exist for its use. It does seem however, that there is considerable evidence in the present study to show that its routine prophylactic use is of equivocal value and perhaps wasteful. In the great majority of cases there is no such indication and in this series satisfactory healing was observed in 96 per cent of the cases without the use of penicillin.

Sulfonamide therapy Much of the conflicting evidence in both experimental and clinical studies on wound healing is a result of a failure adequately to control conditions. We determined from the beginning to treat all wounds uniformly so that there would subsequently be an opportunity to evaluate the results. There seemed to be considerable evidence to support the view that the local use of the sulfonamide drugs in contaminated wounds possessed many limitations. The inhibitory powers of the para amino benzoic acid derivative are well known and the wounds with which we were dealing invariably contained a certain amount of purulent exudate. In addition the relative insolubility of the various drugs results in an exudation of plasma like fluid into the wound which in many instances is detrimental to wound healing. Ten grams of sulfa drug in a wound will frequently give a blood level of only 2 or 3 milligrams per cent and this is out of therapeutic value. For example erysipeloid infections in the periphery of open wounds do not respond well to local sulfa drug medication when it is used alone but they promptly subside on adequate dosages by mouth. It was decided that if an indication for a sulfa drug existed it would be given in adequate dosages by mouth.

As is well known the majority of wounds when they occur on the battle front are dusted with sulfanilamide powder before the first aid dressing is applied. In addition most of them are subsequently treated locally at the time of secondary dressings and almost invariably at the time of débridement. The soldiers also take 4 grams by mouth at the time they are wounded in most instances and the oral medication is almost invariably continued. Intra-

venous sulfa drugs have also been utilized freely at forward medical stations. There is no question but that this has been of tremendous prophylactic value and there is no doubt but that it is the reason that streptococcus cellulitis rarely occurred in the wounded of this war. Septicemia as a complication is extremely rare.

The inclusion of this potent bacteriostatic agent in the armamentarium of the war surgeon has allowed a freedom of action which has permitted many advances in the surgical treatment of these contaminated wounds. One of the single factors which has allowed surgeons to close compound fractures and large soft tissue defects—oftentimes many days after the original wound—is the security afforded by the knowledge that one possesses an agent which successfully combats hemolytic infection and prevents septicemia.

All of the patients in this series received sulfadiazine before and after wound closure. In several hundred cases there was not a single case of systemic infection. In only a few instances was it necessary to open a wound to liberate pus. An occasional wound showing an area of cellulitis would invariably subside on wet dressings and subsequently heal primarily. As evidence accumulated there was little to condone the topical application of chemotherapeutic agents. They are capable of interfering with healing because they act as foreign bodies, they increase the exudation of fluid into the wound and the therapeutic value has never been unequivocally proved.

It should be re-emphasized that whenever débridement had been inadequate in the emergency treatment of the wound there were frequently dire consequences no matter how adequately the various chemotherapeutic agents had been administered either topically or systemically. If on the other hand the essential débridement had been well carried out, the patients arrived in good condition even in those instances in which chemotherapy had been omitted or given in subtherapeutic doses.

The results in these closures were not appreciably altered by either sulfonamides or penicillin locally or systemically when given at the time of closure. The principle of closure of wounds has progressed to the point that it is

SURGERY GYNECOLOGY AND OBSTETRICS

perhaps justifiable to postulate that superficial wounds not closed or covered by graft within 3 or 4 weeks of receipt of injury are being improperly treated. The deterioration of muscle, fascia, tendon, blood vessels, and bone when exposed in an open wound progresses at an alarming rate and most of the complications of wounds can be prevented by covering them with epithelium. This procedure is only possible when accurate and complete débridement has been carried out. In many cases in which débridement has been improperly done or omitted entirely it is feasible to carry out this essential part of the treatment some days later at a fixed installation. It has been stated that the last war only after considerable experience and error. However surgeons of this war were well versed in this particular phase of the emergency treatment of wounds. This factor is undoubtedly of prime importance in the consideration of the excellent results that were

per cent left with a wound requiring any dressing whatsoever. All soft part wounds have been epithelialized either by closure or grafting and practically all compound fractures have been covered with skin either by closure or grafting. The notable exceptions have been wounds of the foot with extensive loss of skin and infection of the small bones of the foot, many of which had persistent and resistant sinuses despite best efforts at closure.

SUMMARY AND CONCLUSIONS

1 The 725 secondary wound closures of so-called contaminated wounds resulted in satisfactory healing.

2 The results in secondary closures are not appreciably altered by either sulfonamides or penicillin when applied locally at the time of closure.

3 One of the most important factors which has allowed surgeons to close compound fractures and large soft tissue defects often time many days after the original wound, is the security afforded by the knowledge that one possesses an agent (systemic penicillin and sulfonamides) which successfully combats hemolytic infection and prevents septicemia.

4 Secondary closure of granulating wounds can only be successfully performed when secondary débridement is performed when secondary débridement is carried out.

The capacity for regeneration and repair as related to wound healing involves certain fundamental principles. To speak of certain wounds of warfare categorically and to consider them apart from the traumatic and surgical wounds of civilian life may lead to certain omissions in the consideration of the general features of wound healing. Present experiences indicate more than ever the importance of a sound knowledge of the basic fundamentals of surgical principles. Careful débridement carried out is still the one most important single treatment for wounds. Without it, no supplementary form of treatment will succeed. Although conditions may be far from ideal the principles of peace time surgery continue to be perfectly valid in times of war.

Opinions concerning the plaster treatment of compound fractures are likewise rather universally being revised. There is no question but that the plaster method as outlined by Trueta is an excellent method for carrying out emergency treatment of wounds under battle conditions, permitting rapid evacuation of wound, with a minimum of trauma. Unfortunately there has been misinterpretation on the part of many as to the applicability and this method has been employed on a large scale in some centers for the definitive treatment.

There were only 5 or 6 instances of secondary hemorrhage. This infrequent occurrence may be attributed to the lack of infection and deterioration of tissue which is prevented by prompt wound epithelialization. There were only 3 deaths which can reasonably be attributed to any operative procedure in 2915 operations performed upon this group of patients. Death in these cases was due to pulmonary embolism. Of 4,471 patients discharged from the surgical service less than 5

MASCULINIZING TUMORS OF THE OVARY

A Clinicopathologic Survey with Discussion of Histogenesis and Report of Three Cases

LALLA IVERSON M.D. Durham North Carolina

INCREASING numbers of masculinizing tumors of the ovary are reported in the literature.

The histological appearance of the arrhenoblastoma group heretofore has occasioned little difficulty in pathologic diagnosis. More confusing are those few cases associated with virilizing symptoms which, because of their microscopic appearance, have been variously termed hypernephroma of the ovary masculinovoblastoma ovarian adrenal rest, or adrenal cortical inclusion. Sometimes classified with the virilizing lipoid cell tumors of the ovary and often indistinguishable from them are the luteinomas or luteomas.

Two of the following cases illustrate interesting variations of the more typical findings of arrhenoblastoma. Case 3 represents both of the above general histologic types in intimate association and is reported for its contribution to the understanding of the histogenesis of these tumors.

CASE 1 Mrs. C. L. D. Duke Surgical Pathology No. 5636. The patient was 37 years of age, white, a nullipara with a previous history of regular menstrual periods and an oophorectomy at 17 years of age. Her present illness was of 18 months' duration, the onset marked by amenorrhea and followed by growth of coarse black hair over her face and chin. In addition to the hoarseness of her voice she noted a tendency to perspire easily, and nervousness accompanied by bitemporal headaches. A slight weight loss and mild lower abdominal pain were experienced during the last few months of her illness.

Patient's height was 63 inches weight 163 pounds blood pressure 144/100.

The patient's face and chin were covered by a growth of hair about 1 inch in length. There was no temporal recession of the hairline. Some coarse hair was distributed about the breasts which were of normal size. A moderately tender cystic mass occupied the right lower abdomen extending up to the umbilicus. Appearance of clitoris and vocal cords were not recorded.

From the Department of Pathology Duke University School of Medicine Durham, North Carolina.

At operation a large cystic mass was found in the region of the right ovary. The left ovary was small and firm. Three small pedunculated fibromyomas were removed from the uterus together with the entire ovarian tumor.

After operation the headaches disappeared immediately and menstruation began shortly after discharge from the hospital. The hirsutism diminished and after 10 years the patient remained free of symptoms of recurrence.

Accessory clinical findings: hemoglobin 90 per cent leucocyte count 8,600 differential, normal. Urea, 18 milligrams per 100 cubic centimeters. Wassermann negative. Glucose tolerance test (50 mgm. of glucose given) fasting 80 milligrams first hour 125 milligrams second hour 118 milligrams third hour 77 milligrams. Urine clear. Bence Jones protein present. Basal metabolic rate +7.

Pathologic examination. The gross specimen consisted of a mass measuring 16 by 8 by 6 centimeters and weighing 1500 grams. The outer surface was smooth except for several cystic areas on the surface. In the center was a well circumscribed semisolid area, grossly hemorrhagic. Numerous multilocular cysts with thin gray walls occupied the rest of the tumor.

The microscopic sections revealed ovarian cortex with primitive follicles at the periphery of the mass. Many large hemorrhagic cysts lined by macrophages containing hemosiderin were noted. There was an imperceptible transition between ovarian mesenchyme and tumor stroma, which for the most part, appeared very edematous and myxomatous. In the myxomatous tissue were clumps and columns of large polyhedral cells with dark staining eccentrically placed nuclei and granular or foamy eosinophilic cytoplasm. These cells were especially abundant about the periphery of masses of sarcoma like tissue consisting of whorls of elongated spindle-shaped cells (Figs. 9, 13, 15 O). The latter in some areas were rounded resembling granulosa cells, and in others ovarian stroma.

The histological picture of the ovarian mass was almost identical with that of 2 cases of arrhenoblastoma with metastases seen in this laboratory (Table I, Cases 38 and 41). One of the latter patients died within 2 years after removal of the primary tumor, the patient just described was free of symptoms of recurrence for at least 10 years after operation.

MORPHOLOGICAL FEATURES OF 41 CASES

Blood pressure	Blood sugar (mgm. per cent)	Basal metabolic rate	Weight of tumor (grams)	Size of tumor (centimeters)	Marked cystic changes	Atrophy of undevolved ovary	Recurrence	Improvement	Remarks
120/70		+7	100	8x7x1	+	+	0	4 mo.	Bone in one portion of cyst wall. Laparotomy 4 mo. after operation showed normal ovary on opposite side
		+95 to 41	990	7	+	+	0	do.	Mucous cyst and rete testis noted in involved ovary
			1030	30	0	0	0		Vaginal atresia, absence of cervix, rudimentary uterus
120/100	87	+30		4x7.5	0	+	0	~4 mo.	Schiller interpreted tumor as adrenal cortical neoplasia. Cells were polygonal and spindle shaped
							3 1/2 yr.	3 mo.	Mixed type at first operation, sarcoma. Sarcomatous 2 second operation
				14				+	Large numbers of interstitial cells
				5	+	+	0	24 da.	Cells spindle shaped and some containing small vacuoles are arranged in epithelial strands
				7x7	0	0	0		Adenoma tubulare
				7	+	+	0		Absence of internal genitalia. Testicular tissue in place of ovary
90/80	54-84		4.8	5x1	+/-	0	Died	0	Autopsy: metastases to liver, mediastinum, adrenals. Pigmentation of skin
115/00				7	+	0	0		Tumor also contained granulosa cells
				5.5	0	+	0	wt.	Grossly hemorrhagic appearance of tumor. Some areas have definite tubules, resembling rete tubules of ovary; in others spindle cells, and in others polyhedral cells
				6x8x6	+		0	mo.	Sarcoma-like in some areas; in others cells arranged in columns. Also collections of polyhedral cells. Great deal of necrosis
				9	+		0	+	Some portions tubular where compact cells arranged in cords. After 2 1/4 yrs. patient still shaving and voice deep. Menstruation regular
					0		0	mo.	Spindle cells, as well as cords, tubules and few areas of polygonal cells, Leydig cells. All symptoms disappeared after 3 mo. Acne
					0		0	+	Looks like seminiferous adenoma
				10x10x6	0		0	mo.	Mostly sarcomatous with spindle cells. Also occasional tubules, but imperfect. Few polygonal cells
			200	10x10	+		+	Died	
			245	5	+		0	4 wks.	
90/60	57			5x3	0	0	0	mo.	Leydig cells mixed with adenoma tubulare
20/80	83	-6			0		Died	0	Primordial cyst; brief period of improvement following hypophysectomy; then sarcoma and abdominal mass. Metastatic interstitial cells. Primary disease simulated Cushing's
94/60		-9		5	0	0	0	mo.-yr.	No abnormal distribution of fat. Pregnancy 7 yr. later
105/90				10x15	0	0	0	+	Epithelium similar to that forming tubular structure. Adenoma-like
115/80		-7		11x5	0	0	0	3 mo.	Acne-Epoid present in large pale interstitial cells

[illegible]

Bence Jones proteinuria has not been previously reported in cases of arrhenoblastoma.

CASE 3. Mrs. C. H. Duke Hospital No B57754. The patient, aged 33 years, colored multipara, was first admitted to an outside hospital because of abdominal swelling

Eighteen months before admission her periods became scanty and amenorrhea ensued. Although a possibility of pregnancy was considered her breasts became smaller. She noted a slight hairline of voice and began to pluck the few coarse hairs which appeared on her chin. These signs were masked by the increased abdominal swelling. At laparotomy, 3

MORPHOLOGICAL FEATURES OF 41 CASES—Continued

Blood pressure	Blood sugar (mgm. per cent)	Based metabolic rate	Weight of tumor (grams)	Size of tumor (centimeters)	Marked cystic changes	Atrophy of uninvolved ovary	Recurrence	Improvement	Remarks
					0	0	0	7 y	All 3 cellular elements present. Few interstitial cells
5/85				20			0	no	Tubular structures as well as sarcoma-like areas
9/85		—		0.90	+	0	0	+	Few interstitial cells at periphery; otherwise sarcomatous
9/80			46.90	28	+	+	0	+	Embryonic rete and cartilage noted
100/80				5x17	+/-	0	0	6 wk.	Ascites, lipid granules in cells
70/00	90			31	0	0	0		Brownish vaginal discharge. Tumor grossly yellow
120/80				10x5	0	+	0	no	Tumor grossly yellow; loss of luster postoperatively
	83	-6	87	7x5	+		0	no	Myxomatous. Pregnancy 1 mo. postoperatively
96/88	95			5	0	+			Fibromyomatous stroma
12/100		+26		3	0	0	0	+	Dermoid cyst on left. Infantile uterus and cervix
					0			28 da.	Acne. Zones of definite epithelial proliferation, as well as sarcomatous areas and clear vacuolated large cells like Leydig cells postop. 3 pregnancies; subcutaneous, normal
			00		+	0	0	no	Cyst lined by columnar epithelium of endodermal origin. Some portions of tumor resemble granulosa cell (homon) carcinoma; also present in tumor
	Normal			9x7	0				Acne. Interstitial cells in soft matrix. Pregnancy together with glycosuria and erythematous symptoms. (Chik) a "pseudobulbous" epithelium, hard 3 "periods." Mother acted 4 days postpartum. Menses gone after 3 months
140/90	72		500	2x5	+		+	Initially	Metastases to peritoneal surfaces, ascites, pleural effusion; improvement after first operation. Died 4 years after onset
44/100	80	+7	300	6x8	+	+	0	mo. yr	Bence-Jones protein present in urine

TOTAL—20 cases.

months after the onset of symptoms an ovarian tumor was found and removed.

The specimen consisted of a single encapsulated tumor mass which measured 7.5 by 7 by 5 centimeters. The outer surface was firm somewhat nodular and contained a thin walled 2 centimeter cyst filled with straw colored fluid. The remainder

of the specimen was a solid tumor like growth. The cut surface appeared homogeneous somewhat fibrous in character and had a slight yellowish discoloration. Scattered through the deeper part of the specimen were small areas of cystic degeneration.

Microscopic sections revealed the tumor to be composed of interlacing spindle-shaped cells with

SURGERY GYNECOLOGY AND OBSTETRICS

Fig. 1 Age incidence in 75 cases of arrhenoblastoma.

elongated vesicular nuclei surrounding large plump cells which were typical of the usual "interstitial cells" in arrhenoblastoma.

Transitions from the former primitive type to the latter differentiated cell were prominent. There was abortive tubule formation (Fig. 3).

The patient improved slightly after the operation but noticed no permanent regression of her symptoms. Her weight loss increased to 50 pounds, and she complained of a loss of libido. Five months after operation a marked ascites and left hydrothorax brought her to the out-patient clinic of this hospital. Because of her progressively weakening condition she was admitted and a diagnosis of Meigs' syndrome was considered. At this time the original slides were requested and a diagnosis of arrhenoblastoma was made.

Accessory clinical findings: Pleural and abdominal fluid no tumor cells. Hemoglobin 12 grams erythrocyte count 4.13 million, leucocyte count, 9,600 with normal differential. Sedimentation rate 41 millimeters per hour. Urine clear. Tuberculin, negative. Total protein 6.3 grams, albumin 3.7 grams per 100 cubic centimeters, globulin 3.6 grams per 100 cubic centimeters. 17 ketosteroids averaged 3.1 milligrams per 24 hours for 3 days.

The patient was operated upon 3 weeks after admission to the hospital. Exploration revealed generalized metastases studding the peritoneum and serosal surfaces of the intestines. The thickened omentum was drawn up to the transverse colon, which was roughly nodular. Biopsy specimens were taken from the omentum, parietal peritoneum,

Fig. 2 Glucose tolerance test in 7 cases of maculopathy ovarian tumor

Fig. 3

Section from primary tumor. Note spindle shaped cells, vascularity and abortive tubule formation. There are numerous gradations between primitive mesenchymal cells and eosinophilic polyhedral interstitial cells. $\times 175$

Fig. 4

Metastasis to fallopian tube. Many fat laden polyhedral cells are intermingled with spindle cells. Note similarity to Figure 3. $\times 75$

Metastasis to appendix. Note eosinophilic interstitial cells submucosa of appendix, more closely resembling those of primary tumor than of tubal metastasis. $\times 75$

Fig 6. Case 3. Lateral view demonstrating distribution of fat. Note hairy arms and legs.

Fig 7. Case 3. Patient before operation (after shaving) showing temporal recession of hair line, loss of hair on scalp, masculine features.

appendix, and tube. The patient died 2 weeks after operation 18 months after the initial symptoms. No autopsy was obtained.

All of the sections showed metastatic tumor the microscopic appearance of which varied greatly. The surface implants were characterized by a friable mass of fibrin, necrotic debris, and large cells resembling "interstitial cells." Infiltrating or metastatic lesions were accompanied by more connective tissue and primitive stroma in the meshes of which were numerous fat laden foam cells (Fig 4). The latter, where found in the appendix, contained less fat (Fig. 5) and more closely resembled the original eosinophilic interstitial cells.

Because of the early metastasis of this tumor and the rapid growth of primitive cells functional signs were slight. Masculinizing symptoms were elicited only in retrospect. The ascites and hydrothorax resulting from the widespread metastases led to a clinical diagnosis of Meigs's syndrome before the second hospital admission. The original tumor presented a relatively benign appearance at a time when there was already evidence (ascites) of early metastasis. The varied and baffling histological picture of the metastatic implants and their dissimilarity to the primary mass re-

Fig 8. Case 3. View of enlarged clitoris, which measured approximately 2.5 centimeters.

Fig. 9. Case 5. Operative specimen including uterus and adnexa. Note small uterus and atrophic right ovary. The left tube roughly marks the boundary of the large thin-walled cyst below and the nodular multicystic tumor mass above.

Fig. 10. Case 5. Gross section of left ovarian tumor viewed from behind. Note thickening of medial portion of large cyst wall. Small nodular masses in cyst wall above. A sarcomatous pattern with absence of interstitial cells. Other small nodules scattered throughout the gelatinous tumor mass above the large cyst contained varying proportions of spindle cells and interstitial cells. Tumor nodules A and B represent the gross picture of sarcomatous and adrenal-like tissue, respectively.

moved 10 months previously emphasize the need for careful clinical and pathologic investigation of every case of primary ovarian neoplasm.

CASE 5 Miss J. S. Duke Hospital No. B54444. The patient, aged 61 years, a single white female of a pelvic tumor of 3 years' duration. Her mother and maternal grandmother had flat hirsutism, but there was no family history of masculinizing tumors. Her father and one brother had diabetes mellitus. The patient stated that her flat hips, large abdomen, "herited" from her father. Physical strength was her development and illness. The essential features of her development and illness are summarized as follows: Age 10 Reached maximum height maturing at same rate as sister. Axillary and pubic hair appeared. Age 13 Menarche periods regular every 38 days lasting 4 to 5 days. Age 15 Weight 136 pounds, maintained for 10 years. Age 25 Increase in hair on chest, upper lip, side of face, controlled by plucking the more unlighty areas. Age 36 Began to gain weight, slowly attaining maximum weight of 155 pounds. Age 35 Flowing hair appeared on arms and legs. This persisted, but there was no change in axillary or pubic hair. Age 44 Forced to begin shaving of hair on cheeks, upper and lower lips, and neck. Age 53 Spontaneous hot flashes. Age 58 (3 1/4 years before admission) Pain in knees and back upon exercise. Abdominal swelling. Diagnosis of local physician arthritis. Fibroid tumor "size of grapefruit." Age 59 (1 1/4 years before admission) Voice became harsh and continued to assume a lower pitch and coarser quality. Age 61 (Six months before admission) Slight vaginal bleeding every day for 5 months. The breasts were reported as having always been small. The patient admitted no change in emotional

make-up or sexual desire with her illness. She received no hormonal therapy. Physical examination revealed temperature, 37 degrees; pulse 79; respirations, 20; blood pressure, 140/80.

The patient was a co-operative, intelligent woman whose manner was conventional and feminine, and whose voice was slightly hoarse but well within a feminine range. The hair was gray or white and quite sparse especially at the temporal region. There was evidence of recently shaved beard over the face and neck (Figs. 6, 7). Heavy black hair was distributed over the shoulders and became quite long and coarse over both forearms and the entire surface of the muscular legs. The pubic hair had a masculine distribution, pointing upward toward the umbilicus. The skin was coarse in texture, and the chest was scented a buffalo distribution of fat. The breasts were extremely small, flat with pale pink nipples and areolae surrounded by a ring of fine black hair. There was no hair between the breasts.

Both vocal cords were slightly reddened posteriorly and moved on phonation. The thyroid was not palpable. The abdomen was slightly protuberant. A firm, mobile, painless mass rose from the level of the umbilicus.

There was moderate hypertrophy of both labia majora and minora. The clitoris was hypertrophied, attaining a length of 2.0 to 2.5 centimeters and a diameter of 1 centimeter (Fig. 8). There was a nulliparous introitus of excellent support. The cervix was small, conical, and firm. The uterus was a palpable mass which appeared to be separate from the large mass which extended into both adnexal regions.

Accessory clinical findings: Roentgenograms of the skull showed no change in the sella turcica. Retrograde pyelograms revealed a slight dilatation of the

Fig. 11 left. Case 3. Microscopic section of tumor nodule A (Fig. 10). Note large polyhedral "interstitial cells" within the sarcomatous tissue. This section resembles primary tumor seen in Case 1. $\times 170$.

Fig. 12 Case 3. Microscopic appearance of edge of a small cyst. Note lining up of interstitial cells in loose connective tissue. Tumor nodule B was composed of a large area such as this. At upper right is seen the periphery of a small mass similar to tumor A (Fig. 11). $\times 85$.

Fig. 13 left. Case 3. Microscopic appearance of a small nodule (C in Fig. 10). Compare with interstitial cells in Figure 11. Note foamy appearance of cells, comparatively slight stroma, marked vascularity and great variation in cell size. $\times 170$.

Fig. 14. Case 3. Microscopic section of peritoneal implant. This was the only metastasis and contained fat-laden polyhedral cells resembling those in metastatic lesion in Case 2 (Fig. 4). Note similarity of these cells to those in masculinovoblastoma (Fig. 15P). Interesting tubular structures characteristic of intermediate types of arrhenoblastoma were not seen in primary tumor.

right pelvis and ureter. Vaginal smear consisted almost entirely of debris and degenerated cells, very rarely an atypical epithelial cell was seen. The smear indicated extreme hypogonadism (Mack, Grade 1). There was some spilling of sugar in the urine during the glucose tolerance test and blood level indicated a decreased tolerance to glucose suggesting a diabetic tendency. Fasting specimen, 108 milligrams $\frac{1}{2}$ hour 110 milligrams 1 hour 180 milligrams $1\frac{1}{2}$ hours 212 milligrams 3 hours 131 milligrams 4 hours 90 milligrams. Blood sugar 103 milligrams total proteins 7 grams chlorides 600 milligrams cholesterol 150 milligrams calcium 8.4 milligrams. Basal metabolic rate -13. Serological tests for syphilis negative. Urinary assays of ketosteroids preoperative 10.9 milligrams per 24 hours postoperative 8.85 milligrams per 24 hours. Preoperative gonadotropins 12 rat uterine units 6 rat ovarian units 4 rat macroscopic corpus luteum units. Postoperative gonadotropins 18 rat uterine units 10 rat ovarian units 4 rat macroscopic corpus luteum units.

The following diagnoses were made arrhenoblastoma, adrenal cortical neoplasm or hyperplasia, adrenal rest tumor of the ovary.

On the 18th hospital day operation was performed. A large cystic tumor about 35 centimeters in diameter was found replacing the left ovary. Following an uneventful recovery the patient was discharged on the 30th hospital day. Four months later she wrote: "Everyone marvels at my quick recovery. The hair on my face and arms is not so thick, about half as much as before the operation. A few new hairs are growing on top of my head where the baldness was taking place. My voice is remarkably better. I can sing a little which I had been unable to do in almost a year and one half."

The gross specimen consisted of a uterus and bilateral adnexa (Fig 9).

The uterus was 8 by 6 by 5 centimeters and contained four small intramural fibromyomas. A soft grayish polyp projected into the endometrial cavity from the superior fundic wall. The right ovary was fibrous indurated, and obviously atrophic. The right tube showed no gross lesions. The left tube was stretched to a length of 10 centimeters as it coursed up to the superior pole of a large 21 centimeter cyst containing clear yellow fluid.

Cells shown to be morphologically similar to theca lutein or paralutein cells (Table III).

Gynandroblastomas, *T*, and luteinized granulosa or theca cell tumors or both, *J*, are both histologically and clinically borderline. Luteomas, *M*, *N* are completely luteinized granulosa or theca cell tumors or both and may be masculinizing or feminizing. The tumor shown at *J* was masculinizing; others histologically similar may be feminizing.

Some workers include masculinizing luteomas within category of virilizing lipid cell tumors or masculinoviolations. This relationship is shown by double arrow connecting *M*, *N* and *P*.

Note morphological similarity of luteoma *M*, *N*, to paralutein cells, *R*, rather than to lutein cells at right of *Q* (more

The lateral and inferior cyst walls were paper thin and numerous tortuous veins were prominent over the surface. Bordering the thicker superior cyst wall was a rough boggy mass which was divided by fibrous septa into several polycystic gelatinous masses. The largest of these was located in the superior lateral curvature of the cyst wall and was composed grossly of grayish-green myxomatous tissue in the center of which were two separate and distinct nodules. The first (tumor *A* in Fig 10) was a firm white tumor 2 by 1.5 centimeters the second (tumor *B* in Fig 10) was a soft bright orange, irregular mass 3 by 2 centimeters. Scattered throughout the myxomatous stroma were numerous tiny yellow flecks of varying size and shape. In some areas these assumed a well circumscribed soft white nodular form with no gross encapsulation. The various septa appeared to converge posteriorly as a band of white fibrous tissue 0.5 to 1.5 centimeters thick, gradually thinning out toward the medial surface of the cyst.

Microscopic sections revealed a chronic vaginitis and cervicitis. The endometrial polyps were characterized by an atrophic stroma and cystic, nonfunctioning glands. The small intramural and surface nodules proved to be fibromyomas surrounded by edematous myometrium.

No ovarian tissue could be demonstrated on the left. Many sections of the cyst wall showed dense collagenous fibrous tissue interspersed with myxomatous tissue. No evidence of teratomatous growth was found. The yellowish nodule in the midst of the wall where the Fallopian tube ended showed a sarcomatous pattern with an imperceptible transition to myxomatous or fibrous tissue at its border. Parts of the more compact regions of the cyst wall were hyalinized and at the edge of the larger gelatinous mass there was an abrupt transition between the fibrous capsule and the myxomatous stroma.

Tumor *A* was composed of spindle-shaped cells with elongated vesicular nuclei which were marked by a clear nuclear membrane and two or three nucleoli. The larger nuclei contained a coarser chromatin network than the smaller more compact nuclei. Gradations toward the interstitial cell described below were frequent. Bipolar strands of cytoplasm containing minute fat droplets were so interlaced that cell borders could not be distinguished. The tumor was not encapsulated but ap-

accurately termed "paraluteinoma"? There is a resemblance between androgen and progesterone-producing paralutein cells, *Q*, and theca lutein cells, *S*, and those of masculinoviolation, *P*.

Former theories relative to the histogenesis of the two types of masculinizing tumors are represented by photographs of a normal testis showing interstitial cells of Leydig, *T*, and of a normal adrenal, zona fasciculata, *U*, showing cells similar to those in the masculinoviolation. The morphological gradations between tumors known to arise from ovarian structures (totipotential ovarian mesenchyme) and the masculinizing tumors strengthen the histogenetic relationship of the theca lutein or paralutein cell to arrhenoblastoma and masculinoviolation.

													1937 Tumor (case of extremely malignant hyperandrogenism?)

peared to end abruptly at its periphery where it was replaced by loose myxomatous tissue. Here the vascularity was greatly increased and clumps of large polyhedral, eosinophilic cells with small round dark eccentric nuclei were seen. Occasional clumps of these cells were included within the sarcomatous mass (Fig. 11).

Tumor B was merely a large concentration of the interstitial cells." Their nuclei were sometimes slightly oval and irregular but were more often round. The nuclear membrane was clear and the chromatin material coarsely granular. The nucleolus was prominent and usually eccentric. In some areas, the nucleus was more compact and finely granular with a hazy nucleolus. Large giant cells with irregular hyperchromatic nuclei were frequent and mitoses were noted in all sections.

The yellow appearance in the mass was due to the accumulation of the "interstitial cells" in concentrations great enough for their lipid content to influence the gross picture. Figure 13 indicates the approximate concentration of these cells in tumor B and shows their arrangement in the myxomatous tissue at the periphery of a sarcomatous nodule. They were seen singly or in groups throughout the entire large tumor mass wherever the loose connective tissue was found. Some of the smaller nodules noted grossly contained polyhedral cells so closely packed in cords and columns that the tumor resembled a luteinoma (Fig. 11). Others of the small nodules showed an arrangement of cells more typical of arrhenoblastoma and very similar to tumor A. One peritoneal implant was noted in a mass of tissue removed separately at operation. This showed three main types of tissue: actual tubule formation approaching the more differentiated type of arrhenoblastoma, a small area of spindle-shaped cells and clumps of foamy cells whose cytoplasm was swollen with fat (Fig. 14).

The clinical diagnosis of adrenal cortical neoplasm was justified in this case of an illness with a relatively insidious onset and long du-

ration in a postmenopausal diabetic. However most of the specimen was typical of arrhenoblastoma, except for the yellowish nodule which resembled adrenal tissue grossly. The identity of the latter with the interstitial cells of the arrhenoblastoma was shown by cytological studies. The influence of this variation on the clinical picture is not known. Its significance will be discussed later.

REVIEW OF LITERATURE

A Arrhenoblastoma The first 25 cases of arrhenoblastoma were summarized in 1933 by Buettner. In 1933 Taylor, Wollerman and Krock claimed the first United States case, which was reviewed 8 years later by the latter two authors (108, 68).

By 1936 the total number of cases was 33. These were comprehensively surveyed by Baldwin and Gafford, who grouped them according to Meyer's classification (81).

I. The adenoma tubulare (testicular) of Pick The most differentiated type, usually unassociated with masculinizing symptoms.

II A middle group with typical and atypical tubular elements and with solid elements.

III Atypical tumors, solid or predominantly solid, with atypical tubular elements.

Their major findings are calculated below.

- 1 Average age 20.3 years range 16 to 33 years.
- 2 Number of cases Type I. Nine (Three showed virilizing symptoms. These contained mixtures of cells represented in the other two types and were not pure examples of "adenoma testicularis"). Type II. Ten (All showed

AND MORPHOLOGICAL FEATURES OF 24 CASES—Continued

Blood pressure	Blood sugar (mgm. per cent)	Basal metabolic rate	Weight of tumor (grams)	Size of tumor (centimeters)	Marked cystic changes	Atrophy of undivided ovary	Recurrence	Improvement	Remarks
14/75				6x3	0	0	Died wk post oper	Initially	Bluish discoloration of face and neck; hemoglobin normal, cords / smaller compact cells mixed with polygonal lipid cells
				7.5x4.5	0		0	4 mo.	Lipoid-containing polyhedral cells
14/70		+9	900	7x6	0	0	0	+	N N-pregnandiol glucoside. N progesterone activity of tumor

93: Klebs (primary hypernephroid blastoma, 9 cases)
Kreutzmann (atypical malignant hypernephroma)

94: Neumann (hypernephroma with virilism)

virilizing symptoms) Type III Fourteen (All showed virilizing symptoms)

3 Frequency of important symptoms
Change in voice or vocal cords, 21 hirsutism, 17, clitoral hypertrophy, 14 amenorrhea, 12 atrophy of breasts 9

4. Recurrence of tumor 5

5 Return of feminism 25 (mentioned in 29 cases) A total of 8 pregnancies 5 in 1 patient, were recorded Earliest improvement noted was resumption of period within 3 weeks

Fifty-eight cases have been reported since 1936, to which we have added 3 cases making a total of 94 cases of arrhenoblastoma. Those reported since Baldwin and Gafford's review are recorded in Table I

B Adrenal rest tumor Luteinoma etc
The second group of masculinizing tumors is called merely virilizing lipid cell tumors by Barzilai. This name was chosen to avoid confusion of terminology in a group in which rigid diagnostic classifications are made by some workers and in which the same diagnostic terms are used interchangeably by others. In this group Barzilai includes luteinomas as well as adrenal rests and "interstitionomas"

In 1908 Bovin recorded the first case of hypernephroma or adrenal rest tumor of the ovary A critical survey of the status of the lipid cell tumors luteomas and hypernephromas was made by Glynn in 1921 who favored a lutein origin of the primary lipid cell ovarian neoplasm

More confusion was created by the indiscriminate use of the term hypernephroma

which may include metastatic nonvirilizing tumors in the ovary For example, Stadiem's review in 1937 of Nineteen cases of hypernephroma of the ovary included no cases which can now be classified as primary virilizing lipid cell tumors of the ovary

In 1939 Rottino and McGrath limited the entire number of virilizing lipid cell tumors to 7 cases. These and the subsequent reports totaling 14 cases were incorporated into a review by Kepler et al in 1944 Seven additional cases of lipid cell tumor associated with masculinizing symptoms can be included at the present time bringing the total to 21 cases. These are summarized with the exception of Neumann's report, in Table II Four other cases classified as adrenal rest or hypernephroma in recent years but not associated with virilism, are included in the chart for the purpose of comparison

Attention must be called to the fact that the above 20 cases include Sellheim's case containing no fat (Case 30 in Baldwin and Gafford's chart of arrhenoblastoma?) Cosaccesco's case which is also included in the series of luteomas by Traut, Kuder and Cadden (112) Saphir and Parker's case of adrenal cortical inclusion in which a definite neoplasm was not found Maxwell's case diagnosed as adrenal rest by Schiller but described as arrhenoblastoma by the author Reis and Saphir's 2 cases of partial masculinization with lipid cell tumor Exclusion of these cases would limit the entire series to 15 cases of complete masculinization with a lipid cell tumor of ovary and classified as adrenal in origin

SURGERY GYNECOLOGY AND OBSTETRICS

Additional cases of masculinization have been associated with tumors which the authors have separated from the above group and have designated strictly as luteinomas or luteomas. Some of this confusion has persisted because some workers justifiably object to the term adrenal rest, believing that there is no final basis for such a histogenetic classification. The proponents of the adrenal rest theory in turn, object to the word luteinoma. Therefore Rottino and McGrath propose the noncommittal term masculinizing lipoid cell tumor.

The following list of luteomas is modified from the series of Traut, Kuder and Cadden who separate the 2 groups histologically

1908	Gardner and McCleary	(Menorrhoea for 8 years)	
1913	Masamitsu	(No virilizing symptoms)	
98	Gordon	(These cases were originally diagnosed as hyperandrogenism, later reviewed by Turnbull and reclassified as luteomas. No virilizing symptoms)	
1920	Gordon	(No virilizing symptoms)	
1927	Wolfe	(Virilizing symptoms)	
193	Cosaccesco, et al.	(See Table)	Classified as adrenal rest tumor by Rottino and McGrath.
1937	Torres	(No virilizing symptoms)	
938	Viana	(No virilizing symptoms)	
1938	Giampalao	(No virilizing symptoms)	
942	Mayer	(Virilizing)	
944	Giordano and Haymond	(Virilizing)	

The histological similarity of the adrenal rest tumors luteomas and luteinized granulosa or theca cell tumors (14 28 109 121) necessitate careful evaluation of the clinical signs for accurate classification. Geist and Spielman (41) suggest that when the tumor is accompanied by signs of masculinization it be considered an adrenal rest tumor and when it is accompanied by evidence of feminizing influence it be termed a luteinized granulosa or theca cell tumor. Such an evaluation of the more recent cases of luteoma may lead to their reclassification as adrenal rest tumor as in the case of Cosaccesco and coworkers.

CLINICAL DATA

Consideration of the clinical features of these tumors is of the utmost importance in understanding their anatomic relationship. In comparing virilizing lipoid cell tumors with arrhenoblastomas it must be remembered that

the significance of the data will change as more cases are added to both groups and as diagnostic criteria become standardized.

Age Figure 1 shows the age distribution of 75 cases of arrhenoblastoma, which corresponds roughly to that of virilizing lipoid cell tumors. Arrhenoblastoma average age, 31.86 years range 15 to 66 years. Masculinoblastoma average age, 31.7 years range 15 to 61 years. These findings do not correspond with the statements of some observers that masculinoblastomas occur in later life.

Race Cases of arrhenoblastoma have been reported in Hindu Spanish, and Latin American women. Five cases of arrhenoblastoma and 2 cases of masculinoblastoma have appeared in the colored race. There is no record of cases occurring in the Orient.

Duration The preoperative course of arrhenoblastoma averages 4 years. The majority of cases are of 1.5 to 2.5 years duration, and the entire series range from 1 to 17 years of symptoms previous to operation. Cases diagnosed as masculinoblastoma average 4.3 years in duration ranging 1 to 17 years and the majority have a duration of 3 years or less.

Weight Fluctuation of weight occurred in 18 of 33 cases of arrhenoblastoma. Of these, 11 showed weight loss and 5 became more obese gaining 20 to 58 pounds. Masculinoblastoma 8 no change 6 gain up to 35 pounds 5 loss of weight. A tendency toward obesity at the onset of the disease is noted in some instances. Loss of weight occurred in 6 of the 7 fatal cases.

Pain abdominal swelling palpable mass One third of the total number of patients with masculinizing tumors complained of pain. Twice that number exhibited objective evidence of the presence of tumor such as palpable mass or abdominal swelling. The symptoms of pain and abdominal swelling or mass are correlated with the size of the tumor except for metastatic cases in which ascites may be present.

There is little significant difference between the number of virilizing tumors located on right or left side.

*The term masculinoblastoma (Rottino and McGrath) will henceforth be applied for the purpose "virilizing lipoid cell tumor" adrenal cortical carcinoma, and "hyperandrogenism."

Loss of libido A loss of libido occurred in approximately 20 per cent of the patients with arrhenoblastoma where this symptom was mentioned. In one patient libido was increased with the presence of tumor. In others the patient experienced a loss of libido only after the tumor was removed.

Available data showed no correlation between libido and basal metabolic rate.

Sterility Some women complaining of previous sterility become pregnant subsequent to removal of the tumor. Pregnancy has occurred in 10 to 15 per cent of the cases of child bearing age following operation. In 2 cases (17, 125) pregnancy and growth of the tumor occurred simultaneously. One infant was a pseudohermaphrodite had an enlarged clitoris and had 4 periods beginning immediately after birth at 28 day intervals.

Hormonal studies Accurate evaluation of hormonal assays is impossible because of the great variation in standards and methods, and because of the absence of control assays. In general there is an increase in androgens and decrease in estrogens and gonadotropins. In absence of recurrence the normal levels are gradually resumed postoperatively.

Virilizing and defeminizing symptoms The patient may give a past history of long standing amenorrhea, of moderate excess hirsutism of masculine habitus or of unusual strength. Some complain of lack of libido during married life or of sterility for many years.

Usually however the onset is more definite progressing steadily for 1 to 4 years until the tumor is suspected. The degree of masculinization is not correlated with size or histological appearance of the tumor except in patients with those tumors classified as adenoma tubulare.

1. Amenorrhea Scant menstruation was present in one patient with arrhenoblastoma (Type I). In all other cases complete amenorrhea occurred including 5 which were postmenopausal. Amenorrhea is usually the first symptom to appear and after the tumor is removed the periods may return within 1 month.

Menorrhagia sometimes precedes the amenorrhea. In some cases it is associated with polyps and fibromyomata uteri in others the significance is not known.

Examination of the opposite ovary at the time of operation reveals atrophy of this organ in less than 50 per cent of the cases. Function was completely restored in all but one case.

2. Hirsutism Hirsutism was present in 85 per cent of patients with arrhenoblastoma. The hair was usually coarse and distributed over the lower forearms, legs, thighs, chest, chin and face. At the pubic region it pointed up toward the umbilicus in typical masculine distribution. It is not unusual for the patient to shave every day. Many of the patients demonstrated a temporal recession at the hairline approaching baldness. The patients who exhibited no hirsutism had no other associated masculinizing symptoms, except for amenorrhea (defeminization). The hirsutism decreases gradually after removal of the tumor.

3. Voice change This sign was present in 62 per cent of the patients with arrhenoblastoma some of whom noticed it only in retrospect. The vocal cords when examined showed reddening, true hypertrophy or no change. A prominent Adam's apple appeared in some instances.

After removal of the tumor the voice becomes higher and the vocal cords diminish in size. In some cases no improvement is noted.

4. Atrophy of breast Seventy per cent of the cases of arrhenoblastoma showed atrophy of the breast. Actual loss of glandular tissue can be determined by careful palpation even in a breast which is not appreciably diminished in size. This symptom regresses rapidly postoperatively.

5. Hypertrophy of clitoris Seventy per cent of patients with arrhenoblastoma show clitoral hypertrophy the clitoris ranging from 2 to 7.2 centimeters in length and averaging about 3 to 4 centimeters. The postoperative regression has not been observed closely. In some cases an appreciable decrease in size has been recorded.

6. Other symptoms Masculine habitus and muscular development, loss of female fat distribution, acne and thickening of the skin are frequently noted and mentioned in both groups of tumors. Rare cases of pseudohermaphroditism, vaginal atresia, infantile uterus and adnexa occur.

The prominent masculinizing symptoms of the lipid cell tumors correspond to the above distribution. Amenorrhea was present in all cases except one which was complicated by other hormonal imbalance: hirsutism 100 per cent, voice change 90 per cent, hypertrophy of clitoris, 72 per cent, atrophy of breasts 50 per cent.

Other clinical data. Some writers have stressed the clinical similarity between adrenal rest tumors of the ovary and of adrenal cortical adenomas, hyperplasia, or carcinoma. They would distinguish masculinovoblastoma from arrhenoblastoma on the basis of certain metabolic changes. The presence of moderate polycythemia in 5 cases of masculinovoblastoma has been recorded, some of these associated with bluish complexions. One case of arrhenoblastoma was diagnosed Cushing's disease. It is not remarkable that these findings are present, in view of the interdependence of the pituitary, adrenal, ovaries, and other endocrine glands.

Dorfman, Wilson, and Peters maintain that cortical tumors appear to resemble in all respects arrhenoblastoma and to secrete male sex hormone or an allied substance with the same action. They state, however, that patients with cortical tumors may in addition have hypertension and diabetes.

In the present series it is found that hypertension is correlated more obviously with age than with the type of tumor present. Comparison of the blood pressure in the two groups shows that only 2 of 9 cases of masculinizing lipid cell tumors had a blood pressure over 140/90, while 8 of 20 cases of arrhenoblastoma had a blood pressure of 140/90 or above. Of the latter group the average age was 47 years.

Furthermore, diabetic tendencies are not found exclusively in the lipid cell group. One case of arrhenoblastoma had glycosuria; another case had elevated blood sugar, and 5 of 6 showed diabetic tendency with the glucose tolerance test. An elevated blood sugar was recorded in none of the cases of masculinovoblastoma, but the glucose tolerance test in 1 case showed a diabetic curve (Fig. 2). A transient glycosuria may be found in both groups of tumors.

Generalization as to metabolic effects cannot be made with the data available and should be deferred until more evidence is at hand.

Other glands may be involved. Hyperplasia of the adrenal glands, a pituitary cyst, and enlarged thyroid glands have been associated with the presence of arrhenoblastoma. The basal metabolic rate varied in the arrhenoblastoma group from -16 to +24. 6 were below normal, averaging -13, and 5 above normal averaging +24. The basal metabolic rate was recorded in 3 cases of masculinovoblastoma: -7, +19, +39.

Improvement and recurrence. All of the cases show regression of symptoms except those which ultimately prove fatal. Ten to 14 per cent of cases of arrhenoblastoma have shown metastases, and 2 in 17 cases of masculinovoblastoma.

Malignancy may be suspected clinically in the presence of a rapidly growing tumor, ascites or hydrothorax or both, loss of weight, or return of symptoms postoperatively after the first period of initial improvement. The prognosis cannot be determined from the histological appearance of the primary tumor. Indeed, the metastatic lesions may vary widely and may not resemble the original mass. Usually the metastatic lesions are sarcomatous in pattern and may be nonsecretory, thus creating some confusion in clinical evaluation of the symptoms unless a careful past history is obtained (Figs. 4, 5, 14, 15A).

MORPHOLOGY

1. *The masculinovoblastoma* is a well encapsulated, round or oval tumor, 2 to 16 centimeters in length, averaging 7.1 centimeters. Only 3 cases in the entire series were above average size. The cystic changes found in less than 25 per cent of the cases are correlated with size of tumor. The ovary is compressed to one side of the tumor or may be absent altogether. The yellowish-orange color is due to the presence of lipoids within the cytoplasm of large polyhedral cells. These cells tend to be arranged in columns within a very vascular delicate fibrous stroma. In some areas near the periphery of the tumor the cells may be clumped together. A fine reticulum is usually

present. Ponceau fuchsin stains may show fuchsinophile granules within the cytoplasm of some of the cells, supposedly indicating androgenic function. Some of the tumors show inclusions resembling granulosa cells, spindle shaped sarcomatous cells, or theca cells.

The variation in appearance of the tumors heretofore reported may be due to the quantity, distribution and type of fat present.

2. *The arrhenoblastoma* averages 12 to 14 centimeters in its greatest dimension, the cases ranging from 2.5 centimeters to an indeterminate size ('fills pelvis,' 'large as a man's head,' etc). Thirty per cent of the cases are above average size and most of these show cystic changes. The tumor may be white or yellow or show hemorrhagic necrotic areas.

a. The adenoma tubulare (testiculare) is said to be the most differentiated form. This tumor is composed of round tubular or gland like structures of varying size often filled with pink staining homogeneous material. The epithelium may be cuboidal or columnar and there is no marked resemblance to testicular tubules. Some cases reported as struma ovarii bear a striking histologic similarity to this type of arrhenoblastoma. When spindle-shaped cells and interstitial cells are found interspersed with the tubular structures some masculinization may occur.

b. The intermediate form contains varying proportions of the sarcomatous cells and interstitial cells. Gradations between the two are seen and abortive attempts at tubule formation are frequent. This type is invariably associated with masculinization.

c. The least differentiated type exhibits a sarcomatous pattern resembling ovarian stroma in which are found clumps or columns of polyhedral cells similar to those comprising the masculinovoblastoma. There is very little tubule formation. Masculinization is found in 100 per cent of these cases.

In a small percentage of cases of arrhenoblastoma various teratomatous inclusions have been found: mucous membrane cartilage, bone, thyroid (adenoma tubulare?) etc. These inclusions have formed the basis for theories as to the teratomatous derivation of arrhenoblastoma.

HISTOGENESIS

Present theories (86, 88) attribute the origin of arrhenoblastoma to certain undifferentiated male directed cells in the rete ovarii, the female homologue of the testis. Masculinovoblastomas are thought by most workers to represent adrenal rests (97) by some, tumors of lutein cells (45).

A histogenetic relationship between the two tumors is suggested by Case 3 in which adrenal like tissue (tumor nodule B) was found associated with typical arrhenoblastoma (tumor nodule A). That these 2 masses are variations of one tumor is evidenced by the following facts:

1. The striking superficial resemblance of the interstitial cells of the arrhenoblastoma to those comprising the adrenal like tissue.

2. The presence of sarcomatous cells and polyhedral cells in other tumor nodules in various proportions. Transitions between the two types of cells are seen.

3. At operation one metastasis was seen which proved to contain masses of lipoid cells, tubular elements and spindle cells so that both primary tumors were represented in the one metastasis.

4. Finally cytological studies showed the cells comprising tumor nodule B and those termed interstitial cells in the arrhenoblastoma to be identical (Table III).

It is of interest that Haffner mentions large masses of interstitial cells in his case of arrhenoblastoma (Table I, Case 6).

If a relationship between these two nodules actually exists it may be asked how one tumor can be derived from two cell rests. The pre-existing confusion concerning the masculinizing ovarian tumors may justify a reconsideration of the available morphological, clinical, experimental and embryological evidence for the present theories of histogenesis and a search for a common ancestor for the two types of tumor.

a. *Evidence for adrenal rest theory.* The term adrenal rest is not without reasonable basis (83). It is conceivable that these cells may be accidentally misplaced in the neighboring gonads during the course of their embryonic descent into the pelvis from their position near the mesonephros (4, 45, 86, 88).

TABLE III—CYTOLOGICAL STUDIES: A COMPARISON OF CELLS OF ADRENAL, TESTIS, AND OVARY WITH THOSE COMPRISING VARIOUS MASCULINIZING OVARIAN TUMORS

Tissue	Nice cell (androgon)	Size nucleus (microns)	Glycogen	Fat (Scharlach red)	Microfibrils	Pancreas (fasten scale)	Reticulum	Hematoxylin and eosin stain
Case 2: Cells comprising yellow nodule	Largest: 13 x 13 Average: 9 x 17	90 x 113 6 x 113	?	Large and small droplets; some droplets in stroma	Fine crystals periphery of cells; some extracellular	Androgen cells seen	Fine fibrils curving around cells	Cell membrane distinct in less concentrated areas; cytoplasm faint or granular; clear nuclear membrane; or eccentric nuclei, granular or coarse eccentric nucleoli
Case 3: Interstitial cells in white mass	9 x 17	7 x 6	?	Large and small droplets	None	None	None	None; less variation
Case 3: Spindle cells in white mass	—	2 x 5	?	Fine droplets; occasional larger clumps	Rare, granular	None	Good reticulum	Cell borders not distinct; many nuclei, elongated, 1-3 nuclei varying with size of cell; nuclear membrane distinct
Cells comprising masculinized adrenoblastoma	27 x 7 to 35 x 14 Average: 7 x 14	8 x 17	?	Large quantities of ethylethylene and extra cellular	Frequent, fine and scattered; few large clumps	No androgen cells seen	Very fine and light reticulum	Uniform; cytoplasm; nuclear distinct when large amounts of fat present; prominent nuclear membrane; eccentric nucleoli; coarse rounded nucleoli
Cells from testis	6 x 11	9 x 9	?	?	?	?	?	Cytoplasm granular; cells uniform; some distinct nuclear membrane, eccentric nucleoli in round or oval nuclei
Testis: interstitial cells of Leydig	5 x 5	6 x 14	None	Scarcely large and small droplets in Leydig cells	None	No reaction	?	Cytoplasm scanty or granular; containing prominent nucleoli; nuclear fairly compact, deeply oval, chromatin fairly dispersed, frequent eccentric nucleoli
Adrenal cortical cells	9 x 14 to 15 x 17 Average: 5 x 13	5 x 11 to 9	?	Packed some fat, clumps	Many large clumps; crystals in some fasciculi	No androgen cells seen	Few strands in some cortex	Morphology varies with position; nuclei vary; rounded but distinct nuclear membrane; distinct nucleoli; some large; granular clumps of chromatin, or many nucleoli
Corpus luteum: lutein cells	—	10 x 13	None	Early, fine droplets; late marked accumulation	None	None	Scarcely reticulum	Cell membrane indistinct; distinct nuclear membrane; many nucleoli, sparse chromatin
Corpus luteum: parietal cells	7 x 14 to 15	6 x 13	?	Many droplets in vacuolar regions	Rare; fine and scattered	No androgen cells seen	Fine prominent fibrils	Cytoplasm vacuolated, heavy or granular; polyhedral, moderately well defined cell membrane; eccentric or central nucleoli in granular nucleus
Ovary: para luteal stromal cells	—	5 x 6	Occasional accumulation about vessels in trabeculae	Fine droplets	None	None	Good reticulum	Nuclei clumped, cytoplasm indistinct; large elongated nucleus; nucleoli; coarse clumps chromatin

Certainly if they occur in the eye (58) and epididymis (36) they may occur in the ovary. Moreover morphological evidence supports the adrenal rest theory in that these tumors bear more than a superficial resemblance to the zona fasciculata of the adrenal cortex, both in their tendency to line up in columns and their fat content.

Further evidence is given by Greenblatt and associates, who compare the lipoids in adrenal rest, arrhenoblastoma, and other tumors to

the adrenal and corpus luteum. Differential studies of fat content of the masculinoblastoma group revealed the cells comprising these tumors to be more similar to those of the adrenal cortex and of adrenal cortical adenomas than to those of the corpus luteum.

In our studies (Table III) the lutein cells were found to be more or less uniform and static. They resembled neither the adrenal cortex, masculinoblastoma, nor interstitial cells of the arrhenoblastoma. Furthermore,

we found little similarity between the latter cells and the Leydig cells of the testis.

In these and other respects our findings agree essentially with those of Greenblatt with the exception that all of the arrhenoblastomas studied by us had minute fat droplets in the cytoplasm of the sarcomatous cells.

If the choice for the histogenetic relative of the masculinovoblastoma lay between the adrenal test and the corpus luteum only the adrenal should be chosen not only on the basis of fat content, but also on the basis of cytoplasmic and nuclear similarities.

b Evidence for ovarian origin of masculinizing tumors

1 Morphological Our cytological studies pointed very definitely to the striking similarity between the paralutein (or theca lutein) cells of the corpus luteum the interstitial cells of the arrhenoblastoma and the cells comprising the tumor nodule B of Case 3. The presence of doubly refractile crystals in theca lutein or paralutein cells the abundance of neutral fats the reticulum and the glycogen distribution justify the assumption of its potentialities as a factor in the histogenesis of 'lipoid cell tumors' of the ovary.

The presence of glycogen and fuchsinophile granules in the adrenal gland (45-8) and their occasional presence in tumors designated as masculinovoblastomas have contributed to the theory that the two tissues are related. However, both of these substances are also found at the periphery of the corpus luteum in the paralutein cells.

Reticulum studies may be of help in the future in differentiating between tumors of thecal origin and those of adrenal origin (112) since the theca cells about the follicle and their luteinized cousins around the corpus luteum both contain a more striking reticulum than the adrenal cortex.

2 Functional Culiner observed. The similarity of these [theca lutein] cells to the adrenal cortex is remarkable and is probably not without significance. Therefore it is pertinent to determine the functional basis for the incrimination of theca lutein cells in the histogenesis of masculinovoblastoma.

This relationship was suggested by Novak in 1940 (86). The endocrine significance of

these theca lutein or paralutein cells is not known but their appearance would seem to leave little doubt that they play an endocrine rôle of some sort.

It is well known that preovulatory secretory changes can be recognized in the endometrium indicating a source of progesterone other than mature lutein cells of the corpus luteum. This finding is associated with the appearance of luteinized theca interna in the ovary.

Furthermore the androgenic effect of progesterone has been demonstrated (51-99) by the fact that progesterone when given to castrated male rats will maintain the prostate and when given to the immature female in large doses will cause clitoral hypertrophy.

In recent years evidence has accumulated for the presence of other androgenic substances in the ovary and the involvement of the paralutein or theca lutein cells in their production (6). Greene Burrill and Ivy (51) have shown that APL will stimulate clitoral hypertrophy in the guinea pig as well as the rat an effect not obtained when the ovaries are removed. Greene (99) has shown that APL at the same time produces increased numbers of interstitial cells (luteinized theca cells) in the mouse ovary and causes a marked growth of the clitoris. Ovaries transplanted to the ears of male rats will maintain the prostate and seminal vesicles for a variable period of time.

Therefore morphological similarities of the paralutein cell to the adrenal cortex and to the interstitial cells of Leydig (more superficial in the latter case) are supported by experimental evidence that androgens are produced in the ovary and more specifically by the paralutein or theca lutein cells.

3 Chemical The correlation is further strengthened by chemical tests which show a rise in phospholipids and cholesterol esters in ovaries during the middle part of the cycle when luteinization of theca interna and formation of theca lutein cells is taking place (112). Not only is a higher concentration of these substances found in the secretory group of ovarian tumors than in the nonsecretory group but a further increase was found associated with luteinization of granulosa or theca cell tumor (57). This corresponds to our

polariscopic studies which demonstrate birefractile substances not only in the adrenal cortex but also in luteinized theca cell tumors interstitial cells of the arrhenoblastoma masculinovoblastoma and the theca lutein cells around the corpus luteum.

4. Clinical. There is abundant clinical evidence that the recently discovered androgenic action of the ovary is directly related to the presence of theca lutein or paralutein cells. Stein and associates in 1935 and 1939 described the presence of luteinized theca interna of multifollicular cysts in 28 cases of amenorrhea (106-107).

Other instances are recorded including Turner's case in which multiple cystic ovaries were found in a case of hirsutism and amenorrhea (114). The symptoms regressed when the ovaries were partially resected. The ovaries showed luteinization of the theca interna and some luteinization of the ovarian stroma.

In the case of Saphir and Parker previously classified as masculinovoblastoma (Table II) the virilizing symptoms were associated not with tumor but with luteinized follicles and an accumulation of cells resembling theca lutein cells. That these changes are due to luteinization and not to fatty degeneration can be adequately determined by Trautkuder and Cadden's criteria of (a) well defined nucleus (b) size of cell (c) enlargement and fragmentation of Golgi bodies, (d) shortening and disappearance of rods (112).

Reis and Saphir's case, also classified as adrenal rest, (Table II) contained a tumor like nodule 2.9 centimeters in diameter which was thought to be corpus luteum. In one corner however there was an accumulation of very lightly stained cells. These were definitely smaller than the cells making up the corpus luteum and had an eccentrically situated vesicular nucleus. Some of the cells showed an empty cytoplasm while in others the cytoplasm was light pink. They differ morphologically from lutein cells although it is possible that these cells are lutein cells (or theca lutein?).

Case 1 of Rottino and McGrath (Table II) had a recurrence of hirsutism and amenorrhea 4 years after the removal of the tumor. The opposite ovary was shown to contain 8 thin

walled theca lutein cysts. It is curious that the original masculinizing symptoms should be caused by "adrenal cortical cells" and the recurrence of symptoms by cells of ovarian origin.

The evidence for the identity of virilizing lipoid cells with theca lutein cells may be strengthened by the examination of plates and reading the descriptions of other cases of masculinovoblastoma.

It has been shown that the tumors of the arrhenoblastoma and masculinovoblastoma types contain cells which morphologically resemble the paralutein cells or the theca lutein cells of the normal ovary as much as they resemble adrenal cortical cells. Experimental evidence has been cited to show that these cells are capable of producing androgens. It has been shown that masculinization without tumor formation is associated with accumulations of these cells, and masculinization with tumor formation is associated with cells that in all respects are similar to theca lutein cells.

5. Embryological and developmental. Granulosa and theca interna cells are derived from the primitive ovarian mesenchyme in the embryo. Tubular structures are seen in both female and male gonads below 15 millimeters (4, 41, 85).

The ovary is derived from the proliferation of coelomic epithelium just anterior to the mesonephros. At about 5 millimeters the embryonic gonad consists of a surface layer of superficial cells and of mesenchyme in which begin to appear radially arranged cell cords. The connective tissue surrounding the cell cords is derived from the mesenchyme. Recent evidence points also to the derivation of the cell cords from the mesenchyme, rather than from invagination of the surface epithelium as was formerly supposed (41). Up to about 15 millimeters the male and female gonads are quite similar although their eventual sex differentiation has long been predetermined (85). After this indifferent stage, the cell cords in the males form the tubular system of the testis and those of the female give way to the follicle (granulosa and theca interna cells). Novak (88) agrees that the theca cells come from the ovarian mesenchyme.

b In the adult ovary, theca lutein or para lutein cells are normally derived from (1) luteinization of theca interna of the maturing follicle and subsequent continuation of this process as the corpus luteum is formed and (2) from ovarian stroma.

It has been shown that the 'Interstitial cell' (theca lutein) is differentiated from the stroma in lower animals and luteinization of ovarian stroma can occur in adult female ovaries producing similar appearing cells. Greenblatt also identifies the interstitial cells of the stroma with theca lutein cells (49). In Rottino and McGrath's case (98) this finding was associated with hirsutism and amenorrhea, which further demonstrates the androgenic action of these lipid cells, whether differentiated from stroma or from theca interna already present.

Culiner's excellent descriptions (26) also show the concomitant differentiation of stroma cells and luteinization of the theca interna. In fact, sometimes the latter merges with the stroma producing isolated islands of theca lutein cells which are seen grossly as yellow specks on the cut surface.

c. Ovarian tumors containing tubular structures and lipid cells may be produced by the radiation of mouse ovaries.

Traut and Butterworth (111) show the development of granulosa cell tumors and luteomas by this means. Geist, Gaines and Pollack's descriptions up to the point of tumor formation correspond with Culiner's observation in the human (39). First the follicle is destroyed; this is followed by proliferation of the theca which merges with surrounding parenchyma; the stroma cells increase in size, become round, and separate in groups or cords (compare arrangement of adrenal rest tumor); luteinization of the theca cells and differentiation of parenchymal cells follows. It is interesting that the corpora lutea are well preserved throughout a finding which justifies its rejection as a potential factor in tumor production.

After 6 months 2 types of tumors are formed: the luteinized functional tumor and the nonfunctioning adenoma caused by invagination of the surface epithelium. Mixtures of both types occur.

c. *Previous problems leading to confusion in literature* The histopathology of the various functional tumors is better understood if the above findings showing the relation between them and the ovary are accepted. The following observations which have previously complicated the histogenetic classification of masculinizing ovarian tumors may be explained.

1 The sarcomatous appearance and the spindle cells which comprise the more undifferentiated type not only of arrhenoblastoma but also of granulosa and theca cell tumors.

2 The gradation of spindle cells to interstitial cells in the arrhenoblastoma.

3 The oft quoted enigma that the most differentiated type of arrhenoblastoma, the adenoma tubulare, has no masculinizing effect while the least differentiated has the most masculinizing effect. We agree with Norris that the adenoma tubulare does not resemble testis. If present embryological and experimental evidence be applied to this group, the tubules may represent simply a nonfunctioning adenoma such as produced by Geist and associates with no histogenetic connection to the testis or to the cells forming the functional part of the tumor or the tubules in arrhenoblastoma may actually be a reflection of their primitive condition as sex cords elements as characteristic of the female gonad as the male.

It is impossible to grade the three types of arrhenoblastoma accurately when this is attempted; there is seen to be no correlation between primitivity and degree of masculinity. In our opinion the androgens are produced by the polyhedral cells in all forms of arrhenoblastoma, as well as masculinovoblastoma or by gradations between the primitive stroma and these cells.

4 Difficulty in strict classification of the functional group of ovarian tumors. Gradations between all types are seen. Banner and Dockerty show that some granulosa cells are included in their series of theca cell tumors. Novak says that the two groups no longer can be easily separated. He further states that partial or complete luteinization of granulosa cell tumors (and more important theca cell tumors) may occur to produce masculinizing lipid cell tumors.

Such a patient was recently seen in this laboratory. In this case complete masculinization occurred in a 19 year old girl. The tumor was 7 centimeters in length well circumscribed and bright orange. Microscopically cyliodroid strands of granulosa cells were noted masses of theca cells and the expected large percentage of lipid cells (Fig 15 J).

Late (94) and Meckler and Black review cases of gynandroblastoma which are merely arrhenoblastomas containing granulosa cells. Case 3 illustrates the completion of the cycle, the transition between arrhenoblastomas and masculinoblastoma.

The observations described are summarized in Figure 15 and the interrelationship of the functional group of ovarian tumors is shown.

SUMMARY

1 Three case reports of arrhenoblastoma are presented 1 with a 10 year follow up showing no recurrence 1 with metastases to liver appendix tubes, and peritoneum and a clinical picture of Meigs syndrome 1 which also contained adrenal like tissue.

2 Evidence is presented to show a possible relationship between arrhenoblastoma and virilizing lipid cell tumors (masculinoblastoma hypernephroma adrenal rest) of the ovary. The case quoted demonstrates both types of tissue in intimate association one metastasis with cells common to both tumors, and cytological studies identifying the cells of the adrenal like tissue as the so called interstitial cells which are found in arrhenoblastomas.

3 The total number of cases of arrhenoblastoma are reviewed with a discussion of the outstanding clinical and pathologic features. These are compared to a similar outline of the cases of masculinoblastoma to show clinical similarities and dissimilarities. Data are presented to show the frequency of metabolic changes in arrhenoblastoma and masculinoblastoma previously considered to be a differential clinical feature.

4. The histogenesis of the masculinoblastoma and arrhenoblastoma groups of ovarian tumors is discussed in detail. The embryology is reviewed to show that the ovary is capable of producing both types of tumor.

Morphological studies demonstrate the similarity between the polyhedral lipid containing cells in both types of tumor and the paraluteal or theca luteal cells of the normal ovary. Clinical functional and experimental evidence is cited to support this relationship. It is concluded that theca luteal or paraluteal cells are directly related histogenetically to both groups of masculinizing tumors. This obviates the necessity of the adrenal rest theory as an explanation of the histogenesis of masculinoblastoma or virilizing lipid cell tumor.

5 It is suggested that the cells comprising arrhenoblastoma are related as follows to ovarian structures: the spindle cells, forming tumors of sarcomatous pattern represent totipotential ovarian stroma; the tubular structures are related to invaginated surface epithelium or to primitive sex cords of the female gonad; the interstitial cell of Leydig in arrhenoblastoma simulates the paraluteal or theca luteal cell. The virilizing lipid cell tumor in its pure form may represent a neoplasm of luteinized theca interna cells or of paraluteal cells and morphologically is more properly termed paraluteinoma. All types of functional tumors probably originate from undifferentiated mesenchyme.

6 A diagram illustrating the interrelationship of functioning ovarian tumors is presented.

THE TECHNIQUE OF THYROIDECTOMY

ALFRED H NOEHREN A.B M.D. F.A.C.S. Buffalo, New York

DURING many years of experience with thyroidectomy, we have constantly made changes in our technique. For this reason a description of our present technique, accompanied by the reasons for its various steps may be of interest. We claim no originality for any of our steps, as most of them are the result of trial and error after observation of other surgeons in various clinics of the world.

Teamwork is especially important in this operation. Our team, consisting of surgeon, assistant surgeon, anesthetist, and instrument nurse, has remained almost intact for many years. Our internes and residents get their experience as second assistants. To have a well trained and experienced assistant surgeon is like having an extra pair of hands because they act and anticipate your wants as though they were being directed by your own brain. A competent anesthetist who takes an interest in thyroid cases and becomes familiar with each patient before operation makes it possible for the surgeon to dismiss from his mind any concern about the patient's condition unless warned by the anesthetist. We depend almost entirely on the judgment of the anesthetist as to whether to do a one stage or two stage operation. An instrument nurse of your own who assists at all operations, looks after the preparations in the operating room, sees that the proper instrument or suture is ready when wanted, relieves the surgeon of much anxiety and allows him to keep his eyes focused on the wound at all times. The instruments, too, should be the private property of the surgeon, should be uniform, should not be used for any other operation, and should be kept in good working condition. For hemostasis, we use the Rankin hemostats throughout.

Our anesthetic of choice is cyclopropane. In patients with heart disturbance, especially those that are fibrillating, ether and oxygen

pentothal intravenously or local anesthesia is used. When there are pressure symptoms, especially respiratory difficulties, an intra-tracheal tube is introduced either through the nose or by direct laryngoscopy through the mouth.

Only the immediate preoperative and post-operative treatment will be described in this paper. The night before operation the patient is given an average dose of 3 grains of luminal. This is repeated 3 hours before the operation. A hypodermic of morphine, grain $\frac{1}{6}$, and atropine grain $\frac{1}{100}$, is given $\frac{1}{2}$ hour before operation. The patient is visited by the surgeon on the latter's arrival at the hospital on the day of operation to be sure no contraindication to operation has developed. No other visitors are allowed, the room is left dark, and the patient is not disturbed. All preparations are made the day before operation. The patient is preferably given a room on the same floor as the operating room and at the appointed time is placed directly on the operating table in her room and transported to the operating room as gently as possible.

The operating room is prepared and the anesthetist and surgeons are ready before the arrival of the patient. When the patient arrives, she is immediately, though without haste, anesthetized, to prevent her from seeing much of the operating room or hearing any of its noises. There should be no unnecessary noise or talking in the operating room.

As soon as the patient is unconscious, her arms are fastened to the sides of her body by winding the drawsheet around them, a sand-bag is placed under her shoulders to hyper-extend the head and push the thyroid forward, the upper half of the table is raised about 30 degrees and the ether screen placed in position (Fig. 1). The operative area is then wiped with ether to remove all fat and sebaceous material from the skin and this is followed by a not too wet application of half strength tincture of iodine. We have never seen any reason for changing to any other antiseptic.

From the Surgical Service of the Deaconess Hospital, Buffalo, N. Y., and the Surgical Department of the University of Buffalo Medical School.

Fig. 1 Position of patient on table

Serious blistering of the skin almost never occurs and infection of the wound is almost unknown about twice in the last thousand cases.

We have tried to make the draping of the patient simple without moving any part of the patient or using special sheets but nevertheless efficient and we believe we have succeeded. A crumpled sterile towel is placed in the hollow on each side of the neck. A towel is placed across the upper part of the chest and still another placed a little higher over this, its upper edge kept taut and fastened on each side of the neck to the crumpled towel and the skin near the upper edge of the operative area with a towel clip and then turned up and fastened to the ether screen with another towel clip on each end. Folded towels are placed diagonally over each side of the neck overlapping below in the midline. A laparotomy sheet is placed over the patient with the operative area appearing in the opening. Finally several crumpled sponges are tucked into any potential openings on each side to cover them and to anchor the draping into position (Fig. 2 a, b, c, and d).

The incision is outlined with the back of the knife about 1 inch above the suprasternal notch and parallel to the folds of the neck. Thus it is made slightly curved with the convexity downward. Whenever there is much protuberance of the skin caused by the underlying goiter the incision is placed correspondingly higher so that after the goiter is removed it is still about 1 inch above the suprasternal notch where it can easily be covered by a string of beads until it fades and becomes almost invisible. A scar that lies on the sternum is very unsightly and difficult to cover.

The incision is made through the skin, subcutaneous tissue, and platysma to the plane of cleavage just above the cervical fascia, avoiding the anterior and external jugular veins that lie on this fascia. If they are injured, they are easily clamped and tied preferably with a surrounding suture but usually they are not injured.

The upper flap is then developed partly by sharp dissection and partly by gently wiping it upward with a sponge. This latter maneuver saves time and locates the bleeding points more definitely thus saving the number of hemostats used. The lower flap is similarly prepared. All bleeding points are tied with No. 000 chromicized catgut. A towel is attached to the edge of the lower flap to cover the skin and the flaps held apart by a self-retaining Crotti retractor (Fig. 2 e and f).

We use chromicized catgut throughout. We are well aware of the arguments in favor of nonabsorbable suture material but feel that by using very fine catgut, No. 000 for superficial ties No. 00 for the rest of the operation we do not cause much more irritation than is caused by nonabsorbable material and without the risk of sinus formation such as we have observed when the latter was used. It is true that these fine ligatures break if too much force is used, but with practice the amount of tension allowed is soon learned and the occasional tear is taken philosophically as the price to be paid for using fine catgut. When such a ligature is once properly tied without tearing it is just as secure as a silk or cotton tie.

A short vertical incision is now made in the midline through the fascia down to the surface of the gland. After a scissors is inserted upward and downward in this plane and the tissues are separated from the gland, the incision is extended upward to the base of the upper flap and downward to the sternum.

The right ribbon muscles are dissected from the gland and retracted with a Parker retractor. The right lobe is grasped with a Lahey forceps and gently pulled upward, at the same time it is gently separated from the surrounding tissues by inserting a finger. This latter must be done very carefully to avoid tearing the veins, especially the middle thy-

roid vein. As soon as this vein appears it is doubly clamped and divided. This vein emerges from the true fascia of the gland and by dividing it, the lobe is further liberated.

If, on inserting the finger the goiter is found to be very large, to extend into the chest or behind the trachea, or to be unusually adherent, it is not delivered until the ribbon

muscles are divided. In such a case, the sternomastoid muscle is liberated by a diagonal incision through its fascia at its anterior border and retracted out of the way after which the ribbon muscles are divided transversely between two Kocher clamps and held out of the way with Lahey forceps. This procedure we have found necessary in only

Fig. 3. left. Treatment of superior pole.

Fig. 4. Pole divided, lobe delivered, row of clamps applied.

about 10 per cent of our patients, but when any difficulty is expected the greater exposure obtained is an added safeguard.

After the right lobe is delivered, the superior pole is prepared by traction downward of that part of the gland, retraction of surrounding tissues, and wiping away any extraneous tissue with a "wiper" (a small folded piece of gauze in a hemostat). Three hemostats are placed on the superior pole just above the gland and the pole divided between the lower two (Fig. 3). Thus the gland is further liberated and it is possible to hold it well over to the left, so that its entire lateral surface is exposed. In cases in which the lobe extends above the line of easy exposure or behind the trachea, the individual vessels at the superior pole are clamped and divided, and the upper part of the lobe allowed to roll out.

At this point it is necessary to decide how much of the lobe to leave behind. This depends upon the age of the patient, the type and toxicity of the goiter and its conformation. We aim to remove all adenomas completely even if they extend far back into the area where the recurrent nerve and parathyroid glands are situated. But in this case the hemostats are placed so close to the tumor that the posterior capsule is left. In general, we leave a thin layer of gland tissue as well

Hemostats are placed along the line of contemplated incision and short cuts made above each hemostat (Fig. 4). The recurrent nerve is not visualized as a routine, but only when we think it is indicated. We believe that there is more danger of injuring the nerve when it is exposed by dissection than there is when its normal location is avoided.

After the outer edge of the lobe is thus mobilized, the isthmus is divided between clamps and the remaining attachments of the right lobe are divided by placing hemostats on the median aspect close to the trachea and working to the right until the lobe is free. All vessels are tied with No. 00 chromogut. At the superior pole, however, a suture is placed around the vessels above the two hemostats, tied the upper hemostat removed, and another tie made around the lower hemostat.

One side is completed before beginning the other side, so that the operation may be terminated at this point, if necessary. After all bleeding is controlled on the right side, a loose tampon is placed in the hollow left by the gland. Enough dissection is made of the left lobe to determine whether operation is necessary on that side. If so the surgeon repeats the same performance on the left side.

If there is difficulty in controlling the oozing from one of the stumps, the lateral border is

Fig. 5 Application of final dressing

sewed to the pretracheal fascia to fold the raw edge over on itself and thus control the oozing. If the field is dry this procedure is not carried out because the raw area is eventually covered by the ribbon muscles and because there is a slight danger of pulling on the recurrent nerve as indicated in a previous paper (1).

The pillow under the shoulders is now removed and the cavity on each side irrigated with a normal saline solution. Thus blood clots are washed out, any residual bleeding is uncovered and any possible infection is washed out or diluted.

If the ribbon muscles have been divided transversely they are sutured with a running lock stitch. The ribbon muscles are now brought together in the midline in two layers with a running suture, first taking in the muscles only and returning as a fascial suture. This makes a good covering for the thyroid stumps and also for the exposed trachea preventing attachment of the overlying tissues.

The incision in the skin and platysma is closed with Michel clamps, care being taken to evert the edges so that the divided edges of the platysma muscle are closely approximated and good healing takes place. If this does not occur the platysma tends to pull the scar apart and widen it. We have found by ex-

perience that Michel clamps alone cause better healing and a finer scar than sewing the tissues in various layers, besides saving considerable time.

A fairly large dressing is placed over the wound and held in place by a long wide strip of adhesive plaster going around the neck and crossing over the dressing in front. Shorter strips of adhesive are placed over the upper and lower borders of the dressing (Fig. 5).

We seldom drain the wounds, even in large intrathoracic goiters. We find that the cavities left are quickly eliminated by pressure from the surrounding tissues. Occasionally we encounter collections of serum under the skin but these can easily be aspirated. The exceptions are cases of uncontrollable oozing or of known or suspected infection. This belief has been a gradual process until we are convinced that the placing of a drain is not only unnecessary but sometimes even invites infection and prevents a perfect scar.

In bad risk cases the operation is done in several stages. In such cases we may merely make the incision or may do one side only. Whenever we are in doubt as to the advisability of continuing the operation, we always play safe and terminate the operation. Thus an opportunity is given to gauge the reaction

of the patient. At the subsequent operation, the incision is quickly and easily opened and the operation completed. However we find it necessary to do stage operations in only about 5 per cent of all thyroidectomies. This we attribute to better preoperative preparation.

A word about intrathoracic goiters. It is very easy to miss even a large downward extension of an adenomatous goiter. We have missed some and have operated upon a considerable number left by other surgeons. This possibility should be thoroughly investigated in every case.

As all the circulation of the intrathoracic portion comes from the regular supply of the thyroid, this should be controlled first. The finger is then gently inserted and swept around the tumor. Care must be taken to be in the correct plane of cleavage. Fortunately there are seldom any dense adhesions to the surrounding tissues and we have never had any trouble from that source. The tumor is now slowly delivered by traction from above and pressure of the finger below. The finger is better than an instrument because it is more easily guided and kept in the right place. If the tumor is too large to be delivered in this way an incision is made in the presenting part of the tumor and its contents usually colloid in character partly expressed. This procedure decreases its size so that it can easily be delivered. Its pedicle is then clamped and divided and the tumor removed.

We no longer aim at high speed in operating but rather to operate gently without any lost

motion or unnecessary delays. In this way we operate more safely and almost as fast as when we try to speed up the operation.

The patient is returned to her room, placed in a semi-sitting position for a few hours, and given enough morphine to control restlessness. Water by mouth is encouraged from the start and usually no intravenous fluids are given. If patients are prepared properly especially if they are given plenty of water and fruit juices preoperatively intravenous therapy is seldom necessary. The patient is kept as quiet as possible with a minimum of fussing. These patients usually get along better on floor service supervised by nurses experienced in thyroid patients than by entrusting them to inexperienced or meddling special nurses.

The initial bulky dressing is changed to a very light one on the day after operation. One-half the clips are removed on the second day and the rest on the third day. Most patients get out of bed on the fourth day and leave the hospital on the fifth day.

Our mortality under this regimen has been 1.2 per cent in our last 1,000 cases. We have had no cases of tetany and no bilateral nerve injuries in these 1,000 cases. With modern methods of preparing iodine-resistant bad risk patients with one of the thiouracil group of drugs or even of curing some of them without operation we hope still further to reduce our mortality.

RESECTION OF THE CLAVICLE

With Particular Reference to the Use of Bone Chips in the Periosteal Bed

HARRIS B SHUMACKER Jr M D New Haven Connecticut

IN order to provide adequate exposure of the subclavian and innominate vessels particularly in operations upon aneurysms and arteriovenous fistulas resection of a portion of the clavicle is often necessary. I do not know who first employed this procedure. Certainly Cooper in 1859 resected the sternal end of the clavicle and a part of the manubrium in approaching an aneurysm involving the bifurcation of the innominate, as did Burrell in 1895. In 1892 Halsted excised the inner third of the clavicle in extirpating a large subclavioaxillary aneurysm. Before 1886 Bardenhauer had utilized resection of the inner portion of the clavicle and a part of the manubrium and of the first two ribs in operating for a number of conditions, including one case in which a tumor involved the first portion of the left subclavian vessels. Through the years it has become increasingly apparent that added safety could be secured in such cases by removal of some of the bony structures overlying the great vessels.

The manner in which the bony defect has been handled has varied. In many of the early cases the excised portion of clavicle was not replaced. Some surgeons have reinserted the bone and fixed it *in situ* by approximating it to the remaining bone with wire or other sutures. The replacement and fixation with sutures of the resected segment of clavicle is subject to many difficulties. Proper immobilization is often not secured and painful nonunions and malunions occur so commonly as to make the procedure eminently unsatisfactory. Holman recently pointed out that the results of superperiosteal resection and discarding of the segment are excellent. My experience is in complete agreement (6).

If the clavicular bed is carefully closed by approximating the periosteum and if the patient is kept flat in bed for 2 weeks with the shoulders held well back and is encouraged to spend a considerable part of the third week lying on his back the results are most satisfactory. Firmness rapidly appears in the region of the missing segment so that long before any evidence of osseous regeneration is evident from roentgenological examination one can hardly tell by palpation that a bony defect exists. Such patients have normal configuration of the chest and shoulders and normal movements of the upper extremities, and are entirely comfortable.

In contrast it has been my experience that replacement of the clavicle often has most unsatisfactory results. In a single instance in which I returned the segment to its bed and fixed it to the remaining ends of the clavicle with wire sutures, a painful nonunion occurred which was relieved only by excision of the segment. A number of other patients who have come under my care after having undergone replacement of a portion of clavicle following excision during the course of operations for aneurysm have had difficulties such as painful nonunion or malunion, conspicuous displacement of fragments, osteomyelitis and poor function.

Satisfactory as are the results from discarding of the resected clavicle and accurate approximation of the periosteal edges it is evident that in many cases regeneration of the bone is slow. Though most of the patients are asymptomatic prior to restoration of bony continuity some have slight discomfort during heavy lifting and other vigorous exercise. Furthermore it seemed desirable if it could be accomplished without significant risk or difficulty to hasten the process of bony regenera-

From the Vascular Center, Mayo General Hospital, Galena, Illinois, and The Johns Hopkins Hospital, Baltimore, Maryland.

Fig. Roentgenograms taken 3 weeks after operation in cases in which bone chips were placed in the periosteal bed. The bone chips are seen. Examination of the ray

films themselves reveals definite callus formation in cases which are portrayed in b and c, though this is not evident in the reproductions.

tion With this in mind a small group of patients were treated by filling the periosteal bed with bone chips secured from the excised segment of clavicle. It is the purpose of this communication to draw attention to this procedure.

The operation was carried out upon 4 patients. In 1 patient resection of the middle third of the clavicle was performed, while in 3 resection of the inner third or half of the clavicle with disarticulation at the sternoclavicular joint was done. In 2 of the latter the sternum was split down to the second interspace. One patient had an arteriovenous fistula of the third portion of the subclavian vessels, 1 a mediastinal fistula between the left subclavian artery and vein, 1 a fistula of the second portion of the right subclavian vessels and 1 an arteriovenous and saccular aneurysm in the anterior mediastinum involving the arch of the aorta and the innominate and subclavian vessels which at operation was found to be inoperable. In each case the clavicle was excised subperiosteally care being taken to preserve the periosteum intact. In 1 case the periosteum was also transected in order to facilitate exposure. The bone was divided with a Gigli saw. The excised segment was covered with sterile normal salt solution. After the vascular surgery was completed the removed clavicle was converted into small bone chips 2 to 3 millimeters in diameter with a rongeur. These were packed into the periosteal bed and the periosteum was

closed over them with interrupted sutures of fine silk. Ordinarily sufficient bone chips could be obtained from a half or two thirds of the resected clavicle. The soft tissues were then approximated in the usual manner with interrupted silk sutures. It should be pointed out that in 1 instance the excised clavicle was inadvertently dropped on the floor and was converted into chips after being autoclaved.

The patients were kept in bed for 2 weeks. For the most part they were asked to lie flat on their backs with the shoulders held well back, although they were allowed to assume other positions occasionally after the first few days. No external immobilization was used. During the third week they were allowed to get up but were encouraged to rest a considerable part of the time on their backs. Definite firmness was noted in the region of the resected clavicle even sooner than was the case in patients who had undergone similar resections without replacement of bone chips.

Oseous regeneration was rapid and complete. Three of the patients were examined 3 weeks after operation (Fig. 1). In 2 of them there was already some evidence of callus formation at this early date. One was examined 7 weeks after operation and showed progressing union (Fig. 2a). In another there was evidence of good regeneration 11 weeks after operation (Fig. 2b). Complete regeneration was apparent in the remaining 2 patients who were examined 16 and 18 weeks after operation (Figs. 2c and 2d).

Fig 2. Roentgenograms taken, a, 7 b, 11, c, 16, and d, 18 weeks after operations in cases in which bone chips were placed in the periosteal bed. It is apparent that excellent bone regeneration is occurring in a and that regeneration is complete in the other 3 cases.

In contrast are the results of roentgenological examination in 10 other patients in whom subperiosteal resection without the use of bone chips had been carried out. In 6 patients there was no evidence of bony regeneration on the last examination made 5, 6, 7, 10, 10 and 13 weeks after operation. One showed only a small amount of callus formation 27 weeks postoperatively. Another had evidence of a little callus at each end of the remaining clavicle 4 weeks after resection but had not achieved union 34 weeks after operation, at which time it appeared that the ends of the bone were becoming eburnated. One patient exhibited excellent regeneration in 8 weeks (Fig 3a). In 1 there was evidence of progressive union 12 weeks after operation and excellent union 29 weeks after operation (Figs. 3b and c). Thus when these patients were

examined at intervals of from 5 to 34 weeks after excision the majority showed no callus formation. Furthermore when regeneration occurred it sometimes proceeded from the ends of the remaining bone rather than through out the periosteal bed as was the case with those in whom bone chips were used. In one such case it appeared that union would not be achieved because of eburnation of the bone ends (34 weeks after operation) while another proceeded to excellent bony union (Fig 3c).

DISCUSSION

In many operations in the clavicular area and in the anterior mediastinum essential exposure is facilitated by clavicular resection. This is particularly true in cases of aneurysm and arteriovenous fistula of the subclavian, innominate, and internal mammary vessels

Fig. 3 Roentgenograms of patients in whom there was good bony regeneration following excision of portion of clavicle with simple closure of the periosteum a, taken 8 weeks after operation shows excellent regeneration b,

taken weeks after operation upon another patient shows good regeneration of bone but incomplete union in the medial portion of the area from which bone was removed. In c, union is seen to be complete 29 weeks after operation.

Frequently section or resection of the clavicle is necessary in explorations of the brachial plexus. In the latter cases simple osteotomy often suffices and excision of a segment of clavicle is unnecessary in order to secure adequate exposure. Although I have had little experience with clavicular section for exploration of the brachial plexus, I have seen many patients who have undergone such procedures. It is my impression that difficulties with maintenance of position of the fragments with various methods of wire and screw fixation are sufficiently common to justify inquiry at least, into the advisability of resection of a segment of clavicle instead.

When a portion of clavicle is excised the incidence of difficulties in maintaining position in securing union, and in avoiding pain following reinsertion of the intact segment and fixing it in place with wire sutures is so high as to make its use unwise. Although resection and discarding of the excised segment of clavicle with periosteal closure give excellent cosmetic results, stability and good function at least for all but strenuous work and exercise in many instances bony union is long delayed. My own patients have not been followed long enough to permit me to say what percentage will eventually obtain good osseous union, nor are such data available in the literature. In spite of the excellent functional results from such operations it is believed that the simple procedure of replacement of bone chips in the

periosteal bed is worth while. From the small group of cases so treated it appears that such operations are followed by good cosmetic and functional results and by rapid and complete bony restoration.

The successful use of bone chips in the periosteal bed in these cases brings up the question of application of this principle in other situations where bone must be excised in order to facilitate exposure. It also raises the question whether this method may not prove a simple and successful one in cases of old ununited fractures of the clavicle.

CONCLUSIONS

1 Experiences are reported in 4 cases of clavicular resection in which rapid and complete restoration of bony continuity followed replacement in the periosteal bed of bone chips which were obtained from the excised portion of the clavicle

2 The usefulness of this procedure in explorations requiring resection of a segment of clavicle is discussed as well as certain other possible applications of the method

CANCER OF THE CERVIX

THE two papers appearing in this issue of SURGERY GYNECOLOGY AND OBSTETRICS describing the radiation reaction of cells seen in the vaginal secretion in cases of cervical carcinoma, represent a potential advance in the treatment of patients with this disease. The first paper concerns the distinguishing characteristics of cells exposed to radiation and their differentiation from unirradiated cells both normal and malignant. The second paper indicates a possible method of prognosis in cervical cancers under treatment by radiation. While the patient is still receiving radiation treatment, by examination of the vaginal secretion with special attention to the presence or absence of radiation reaction in the normal cells, a prognosis on the ultimate success of the treatment may apparently be obtained. It may be of basic importance that changes in the *normal* cells rather than disappearance of the malignant cells is the significant factor in prognosis.

Patients in whom malignant cells were found to persist in the smear for some time nevertheless did well if the normal cells showed an adequate response to radiation on the other hand those patients in whom the normal cells showed no response to radiation did poorly, even though the malignant cells disappeared.

Though admittedly the follow up on this series is too short to justify a final conclusion as to the ultimate prognostic value of the vaginal smear in irradiated cases nevertheless the early work of Gluecksmann and Spear on the one hand and of Warren, Meigs and associates on the other hand would substantiate Graham's observations.

If after a longer period of follow up this method still offers the same prognostic accuracy another definite forward step in the treatment of cervical cancer will have been established. Heretofore it has not been uncommon to find after what was believed to be a satisfactory clinical response to radiation that cancer nevertheless recurred. Until now there has been no practical way of determining the response to radiation at the time of treatment. In patients showing minimal response to radiation by vaginal smear it is possible that roentgen therapy should be abandoned and a surgical attack attempted.

In the past few years the attitude toward radical surgery for carcinoma of the cervix has undergone considerable modification. It is recognized that simple total hysterectomy is not the proper operation. Metastases to lymph nodes may occur early in the disease and therefore this operation is not adequate. Taussig and Bonney have shown that the surgical removal of lymph nodes may cure 1

of 5 patients. Taussig's operation for the transperitoneal removal of nodes after radiation treatment of the local cervical growth has proved satisfactory in the hands of both Taussig and Morton. Recently at the Massachusetts General Hospital and the Pondville Hospital, a retroperitoneal operation has been advocated for the removal of these nodes and this approach has been found more satisfactory than the transperitoneal method of Taussig. The radical surgical operation has been proved to be safe for in our hands one hundred patients have been operated upon without a single postoperative death. The bugbear of ureteral fistula has been overcome by greater care in preservation of the ureter's blood supply.

If Graham's work is corroborated the surgeon is offered an opportunity in radiation resistant cases to operate, rather than wait upon the results of radiation as he has had to

do in the past. Radical operation in the group of patients may salvage a certain percentage that would otherwise be lost. Another possibility is that by the use of the vaginal smear during radiation treatment the radiologist may be able to increase the dosage of radiation in certain resistant cases.

Advances in methods of radiation treatment have also been made and Merritt's work, on the use of the vaginal cone, has been corroborated and advanced by Behney. In a disease for which progress in treatment seemed almost at a standstill ten years ago the outlook is more encouraging. Early diagnosis of cancer of the cervix by vaginal smear as described by Papanicolaou, together with the possible selection of proper cases for radiation or surgery—as suggested by Graham's work—constitute two definite advances in the control of cervical cancer.

JOE VINCENT ALKIOS.

THE SURGEON'S LIBRARY

REVIEWS OF NEW BOOKS

THE second edition of *Mason and Zintel's Preoperative and Postoperative Treatment*¹ is a well balanced monograph concerned with the modern care of the surgical patient. Its greatest value will be for the younger men entering on their surgical service.

The new edition is divided into the general conditions which concern all surgical patients and considerations of the regional and special divisions of surgery. The chapters on care of the cardiac, hypertensive, and diabetic patients are excellent. Others, as the sections on anesthesia and treatment of shock, are very brief and limited in their scope and give only a superficial summary of these subjects.

The indications for use of blood, the technique of typing and discussions of blood grouping are practical and concise. Postoperative pulmonary complications are presented in an excellent manner. The section on the care of superficial burns is mainly devoted to the triple dye treatment, and the use of antibiotics is only mentioned in a casual manner. The bibliography of this chapter is brief and contains only one reference as recent as 1944, four of 1943 and the remaining fourteen to papers written before the war.

The chapters devoted to the surgical specialties or specific regions of the body are generally good and the methods advocated are sound. The sections devoted to the care of the thyroid patient and that on thoracic conditions are practical and broad in their scope, other sections as those on stomach and small intestine, are brief and rather superficial. The chapters on physical medicine and trauma are of little value to a student desiring detailed information on these subjects.

The volume is well illustrated and most chapters include a satisfactory bibliography. The appendix is a helpful guide to the laboratory findings in blood and urine in health and disease. HARVEY S. ALLEN.

HIS thorough knowledge of electrocardiography is clearly reflected in the extensively revised and expanded second edition of Doctor Katz's book *Electrocardiography*². The volume deals rather completely with the entire subject and is one of the best single volumes yet presented on this still young subject. The book is divided into three sections: the

first dealing with the theory of electrocardiography, the second with a description of the normal electrocardiogram and the tracings characteristic of many pathological conditions and toxic states, and the third section dealing with a description of the arrhythmias.

Of the three sections the first is probably the most difficult to read and understand and some beginners will no doubt become a little discouraged in trying to master this material. The text, however, in the second and third section is to be recommended even though at times the discussion tends to become verbose. The handling of the subjects ventricular strain, coronary insufficiency and digitalis effect, with the differential diagnosis of each, is excellent.

Doctor Katz makes three noticeable exceptions in terminology from that recommended by the American Heart Association. They are the use of axis shift instead of deviation, intraventricular block instead of bundle branch block, and the use of first and second degree arteriovenous block instead of incomplete block and incomplete block with dropped beats. These deviations will no doubt be criticized by other authorities on the subject.

The evolution of the electrocardiogram in recent myocardial infarction is exceedingly well presented and illustrated and will be of great value to the beginner as well as the advanced student. Doctor Katz is not in favor of the use of exercise tests etc. in the attempt to diagnose transitory coronary insufficiency. The subject of interference and dissociation remains a difficult subject for the average student to master and a difficult subject for Doctor Katz to present. If the reader, however, will carefully read and reread this chapter he will have certainly a fairly good understanding of these complex arrhythmias.

Summary tables are used throughout the second and third sections which concisely present the salient features of normal and abnormal deflections of specific patterns and of various arrhythmias. The author points out in his preface that these will be of value to the beginner, indeed even many of the so-called advanced students will welcome these tables.

The electrocardiograms are numerous, excellent and described in detail. However it is unfortunate that in many instances the print is so small that reading these descriptions is difficult. There is an extensive bibliography at the end of each section which adds greatly to the value of this work to the advanced student.

¹PREOPERATIVE AND POSTOPERATIVE TREATMENT. Edited by Lt. Col. Robert L. Mason, M.C., A.U.S., and Harold A. Zintel, M.D. 2d ed. Philadelphia and London: W. B. Saunders Co. 1945.

²ELECTROCARDIOGRAPHY: INCLUDING A ATLAS OF ELECTROCARDIOGRAMS. By Louis N. Katz, A.B., M.A., M.D., F.A.C.P. 2d rev. ed. Philadelphia, Lea & Febiger. 1945.

anatomical clarity for schematic vividness. The treatment of the inguinal region, mesenteries, blood vessels, kidneys and suprarenals is highly conventional, resembling models rather than dissections themselves.

The schematic drawings of the abdominal layers are architectural achievements but take considerable liberty with the true constitution of the parietal laminae.

In the volume on the pelvis and perineum color is again lavishly and helpfully used, but the author's order of plates is seemingly quite haphazard for a section of anatomy in which a knowledge of serial succession is of the fundamental importance. While the layers of the pelvic and urogenital diaphragms are shown in schematic clearness, they are not portrayed accurately. Fascial layers of the perineum are shown in disjunction, not as strata continuous with layers in adjacent regions. The relations of the pelvic viscera to their ligamentous, fascial, and diaphragmatic supports would be of little use in training critical students for the practice of gynecology, urology or proctology.

In the series of plates depicting the anatomy of the thorax, the schematic method is utilized to greater advantage, since much of the important anatomy of the thoracic cage and of its visceral, vascular and nervous contents may be taught from transverse and sagittal sections and from surface projections of organs.

In the sections on the upper and lower extremities, the figures which show the areas of muscular attachment on the bones are fundamentally similar to those found in the standard textbooks, atlases and manuals of gross anatomy. Here the order is the logical one of successive layers, from cutaneous nerves, superficial veins, and fascial sleeves, through progressively deeper layers of muscle. In the simpler figures, for example, those dealing with the synovial sheaths of the hand and foot, the schematic plan is utilized to great advantage but when the same device is employed to show the tendons, nerves, vessels, and muscles, the collection of transected structures forms a somewhat bewildering assemblage.

The colors employed in the illustrations seem unnecessarily garish. However the reader cannot blame either the author or illustrator for indulging in such innocent gaiety when chromatic feasts of this nature are so rare in the staid history of anatomic illustration.

Taken as a whole, *Illustrations of Regional Anatomy* is a useful adjunct to the student's regular anatomical library. It treats of the kind of anatomy which is customarily presented in charts. Its graphic character is analytical of the standard type illustration or take-apart models found in all fully equipped laboratories. The volumes of figures serve as a link between the standard atlas which the student uses at the dissection table and the blackboard drawings which are regularly a feature of the lecture in gross anatomy.

BARRY ARNOX.

IN the 200 hundred page monograph *Early Ambulation and Related Procedures in Surgical Management* by Leithauer the author reviews the history and development of early ambulation, making a claim for priority. Early ambulation as described consists in requiring the patient to be out of bed, standing, coughing and walking at frequent intervals starting from 4 to 8 hours after operation. These brief periods of activity are separated by longer periods of rest flat in bed. Profound shock, uncontrolled hemorrhage, imminent death, rectus muscle incisions and improperly closed incisions are believed to be the only contraindications to this type of treatment.

Pulmonary, circulatory and gastrointestinal complications are discussed in some detail and are believed to be eliminated or reduced by early ambulation. Psychological and economic advantages accrue under this management.

The author's routine care is described, including types of incision, suture material, and wound closure believed essential if early ambulation is to be used. His personal experience in the case of 549 patients in whom early ambulation was used is summarized. These reports are wholly favorable and a strong argument is made for this type of management.

Many surgeons will find objection to early ambulation in such cases as active peritonitis or empyema of the gall bladder. The method, however, deserves the careful study of all surgeons.

THOMAS C. DOUGLAS.

THE moderately sized book *Treatment of Bronchial Asthma* is written by many authors. It is made up of 23 chapters, some of which are excellent and some quite inadequate. The outstanding chapters are probably those on the history of bronchial asthma, statistics, anatomy and physiology, house dust, pollen and fungi, food allergy, parasites, psychogenic factors, differential diagnosis, surgical treatment, complications and cardiac asthma.

The "Treatment of Bronchial Asthma," the title of the book, is hardly adequate. The information given is accurate but insufficient. Indications and directions for treatment are not clear enough for the general practitioner or medical student. It is unfortunate that there are no case reports, and that although directions for treatment of patients allergic to pollens or house dust are given, practically nothing is said about those allergic to horse dander, cottonseed, farm dusts and other important causes of asthma. The use of tetanus toxoid is not mentioned. By including these omissions in a second edition, this book would be a must in the library of all interested in asthma and related subjects.

LEON UNGER.

EARLY AMBULATION AND RELATED PROCEDURES IN SURGICAL MANAGEMENT. By Daniel J. Leithauer, M.D. F.A.C.S. Springfield, Ill. Charles C. Thomas, 1941.

TREATMENT OF BRONCHIAL ASTHMA. By Vincent J. Darbo, M.D. and Hugo J. Engelhardt, M.D. F.A.C.P. With chapters by 15 contributors. Philadelphia, London, Montreal J. B. Lippincott Co. 1941.

FROM the University of Havana *Clinica y Laboratorio* is a critical interpretation of the methods used in the clinical laboratory and the results thereof. Sections are devoted to all of the subjects usually considered in a work of this type. In addition, much space is given to the field of mycology. There are chapters on biopsies, allergy tests and medical toxicology which are necessarily incomplete. An extensive bibliography refers to both the English and Spanish literature, and the author frequently appraises the value of the references listed.

Pittaluga's aim is to acquaint medical men with the value of the standard laboratory procedures, and he does not intend to describe in detail all of the methods discussed. When several methods are available for performing a given examination he discusses their relative merits and expresses his preference. To aid the clinician in intelligent utilization of the laboratory background material from the fields of physiology, biochemistry and pathology is supplied.

This book is not to be regarded as a manual of laboratory procedure nor as a complete treatise on clinical pathology but serves well its expressed purpose of acquainting the general medical man with the usefulness of the various clinical laboratory methods.

AURA P. DUKE.

THE compendium *The Chest* by Dr. Leo Rigler provides a review of thoracic roentgen diagnosis and is likewise useful as an atlas for ready reference, since its 350 odd pages are replete with illustrations of superb clarity and photographic excellence.

The entire thorax is not included in specific detail, the heart and diaphragm, for example, are discussed only insofar as they are implicated in considerations of other thoracic viscera or regions. From the standpoint, however, of the physician or surgeon interested in chest diseases the field is well covered.

Roentgen examination methods and techniques are concisely presented from the practical viewpoint of the needs of the clinician, the indications, advantages and limitations of each means of study being given. A minimum of technical physical data is included.

Twenty-five pages are devoted to the normal chest, the anatomic variants or anomalies which may have no clinical significance are discussed and numerous extraneous causes for the production of artefacts which should not be interpreted as intra-thoracic lesions are pointed out. Thoracic physiology is briefly reviewed and the principles governing mediastinal shift and mediastinal movements as in obstructive emphysema, are pointed out.

The pathologic conditions presented and discussed include principally those of the bronchi, lungs, mediastinum, and pleura. A brief, concise, general presentation of the subject matter in didactic style

precedes the main feature in this volume which is illustrative roentgenograms. A detailed description of these illustrations accompanies them on opposite pages.

If criticism is to be made of this work it would be in the arrangement of the didactic introductory material in its relation to the illustrations. They do not always follow the same scheme of presentation. For example, the discussion of the 'normal chest' is interrupted at page 36 by numerous illustrations to be resumed only on page 44. This factor is minimized by suitable annotations directing the reader to the proper page for preservation of continuity. Errors in the body of the subject matter might be pointed out but they are minor and not consistent.

This volume is beautifully printed, the roentgenograms are faultlessly reproduced, and to have secured such admirably clear cases for illustration and in such generous numbers is indeed remarkable. The purpose for which this material was compiled has been wholly satisfied.

HIRAM T. LAWSON.

A VERY important book for general surgeons and gynecologists has been written by Richard Te Linde.* He has endeavored to describe nearly all methods of operative approach to gynecological conditions simple and complicated. By using his own art and also selecting the drawings from well illustrated articles by other operators he has covered the field beautifully. There are very few criticisms possible in a volume of this size and magnitude. The book is unquestionably up-to-date, and all new operative methods are well described and illustrated. It does not purport to be an atlas for besides the illustrations both line drawings and half tones there is an extensive text giving descriptions of the lesions, their symptoms, diagnosis, etiology and treatment.

For the practitioner who is dependent upon text books for aid in attacking a given problem this book gives excellent advice, very satisfactory reviews of the current opinions and sound advice as to procedures, with these are excellent illustrations of the surgical technique. In most texts of gynecology satisfactorily illustrated operative technique is omitted but in this book operative technique is stressed.

This is an excellent book and one that can be recommended with great enthusiasm.

JOE V. MIXON.

THE small monograph, *Diseases of the Basal Ganglia and Subthalamic Nuclei*, reprinted from the *Oxford Loose Leaf Medicine* has recently been published in attractive book form and it is an up-to-date treatise on a very difficult subject by one of the country's best informed neurologists and investigators of neurologic problems. Anyone who would attempt an elucidation of the subject of disease of

*THE CHEST. A HANDBOOK OF ROENTGEN DIAGNOSIS. By Leo G. Rigler, M.D. Chicago, Ill.: The Year Book Publishers Inc., 1946.

*OPERATIVE GYNECOLOGY. By Richard W. T. Linde, M.D. Philadelphia, London, Montreal. J. B. Lippincott Co., 1946.

*DISEASES OF THE BASAL GANGLIA AND SUBTHALAMIC NUCLEI. By D. Denney-Brown, M.D. C.F.B., Dr. Paul F.R.C.P. Edited by Hiram A. Christian, A.M., M.D., LL.D., Sc.D. (Hon.), F.A.C.P. (Hon.), F.R.C.P. (Can.). New York: Oxford University Press, 1946.

SURGERY GYNECOLOGY AND OBSTETRICS

the basal ganglia must necessarily be not only a clear thinking person, but, more simply, a brave man. This work after a brief consideration of the anatomy, physiology and pathology of the basal ganglia in man, discusses individually as to definition, etiology, history, symptoms, physical findings, course and treatment, the following diseases: paralysis agitans, progressive atrophy of the globus pallidus, the various forms of parkinsonism, hepatolenticular degeneration, dystonia musculorum deformans, the athetoid states, Huntington's chorea, and other forms of adult chorea. The discussion of hepatolenticular degeneration (Wilson's disease) is a particularly lucid and instructive one. Though the section dealing with this syndrome occupies only 21 pages, the reader is given full understanding of the clinical signs, and particularly of the pathological changes

in the brain and liver. In that section, as throughout the book, the older, "basic" literature has been studied and quoted freely as well as all the pertinent literature of a more recent date.

This reviewer is left not only with a clearer knowledge of the fundamental signs and changes in the disease states of the basal ganglia, but also with the rather depressing knowledge that while more and more information is added yearly to the field, mental approaches to the causes and effects of these diseases are still little that can be accomplished by either medical or surgical treatment.

This book is not easy reading. It is not one for the casual reader but rather one for the student specifically interested in the subject. It can be used as source material not only because of the original content, but also because of the exhaustive bibliography which is appended.

COLLECTIVE REVIEW

ANTISEPSIS AND DISINFECTION IN SURGERY

EDWIN J. PULASKI, M.D., Major, M.C., A.U.S., San Antonio, Texas

ALTHOUGH the application of drugs to wounds was practiced by the ancients it was not until the classic work of Lister (43) that the full significance of bacterial infection in wounds was appreciated. Modern surgical procedures are based on Lister's observations that suppuration does not take place provided access of bacteria from without is rigidly prevented. Oliver Wendell Holmes and Semmelweis, at an even earlier date, had concluded that puerperal fever could be prevented by aseptic precautions.

Lister achieved the elimination of infection from cases of compound fracture by the use of a crude carbolic acid, but not all attempts to prevent infection by this means were uniformly successful, and he later deprecated bringing this corrosive substance in contact with tissues (43).

Ever since the discovery by Pasteur of the bacterial etiology of infections, many substances have been recommended for their antiseptic or disinfectant properties. Each year finds many additions to the list (40). In most cases these represent efforts to provide an ideal antiseptic.

Antisepsis and disinfection are far from being simple subjects, and advances in our knowledge of the basic facts governing the action of antiseptics, together with changing concepts in the approach toward achieving sterilization of wounds, have added measurably to the complexity of the subject. The discovery of sulfonamides and antibiotics has been largely responsible for these developments and an enormous literature has accumulated on many aspects of the problem. Medical curricula

too often are weak in presenting this subject in spite of its important bearing on surgery.

Many antiseptics are used today solely because of tradition, a matter of habit, or because of current popularity. There is a general misconception as to what can be done to bacterial flora in the tissues by these agents. Since many compounds are used to disinfect surgical instruments or excreta and act as protoplasmic poisons, there are workers who consider all such agents in this category and therefore unsuitable for application to wounds.

In view of the many misconceptions relative to antisepsis and the plethora of statements regarding them, the author will try to present a review of the subject in a systematic manner in the following order:

1. Mode of action of antiseptics.
2. Need for antiseptics and disinfectants in surgery.
3. Those agents producing disinfection by physical means.
4. Antiseptics acting primarily by chemical activity e.g. the surface antiseptics.*
5. Antiseptics which act by interfering with the specific function of the bacterium (such as sulfonamides and antibiotics).

MODE OF ACTION OF ANTISEPTICS

The terms disinfection and sterilization are often used as synonyms. The accepted definition is that after disinfection or sterilization there contains no living bacteria, protozoa, etc. Disinfection usually implies the use of antiseptics to destroy micro-organisms. Most of these are used by reason of their nature are also

*Brooks Army Medical Center, Dept. of Surgical Research, San Antonio, Texas.

harmful to tissues. Antiseptics are substances which in some cases kill bacteria and in others simply prevent their multiplication, according to the character of the product and its method of use. Thus, an ointment may be called antiseptic if it prevents the multiplication of bacteria, but a mouth wash which remains in contact with the tissues for only a short time must actually kill bacteria to be so labeled.

Few substances are germicidal in body tissues, so that the term disinfectant is reserved for agents used to destroy micro-organisms in inanimate objects or on the intact skin, while the term antiseptic is applied to those substances used to control infection in the body. The term chemotherapy was coined by Ehrlich and it is today accepted to mean the antiseptic use of a substance which inflicts maximal injury on the bacteria and minimal injury on the tissues of the body.

The ideal antibacterial agent would be one which was powerfully germicidal against all pathogenic bacteria in that bodily environment where its action was required but at the same time completely inactive against the tissues of the body. A number of other characteristics are highly desirable, as follows:

Physical properties. The substance should be in a form permitting rapid delivery and easy access to the area needed. Thus, it must be soluble in tissue fluids well beyond effective levels and it must be capable of penetrating beyond tissue exudates to the site of the offending organisms. The vehicle in which it is applied must be inert and also release the drug in effective concentrations on contact with tissues.

Stability. The substance should be stable on exposure to light, air, temperature changes, humidity and transport.

Low Toxicity. It should lack any tendency to irritate tissues or to cause any adverse reaction on general administration.

Elimination. It should be easily removed from wounds or dressings when used locally.

Cost. The substance should be comparatively easy to prepare at low cost.

It is apparent that no single antibacterial substance so far available meets all these requirements.

For the proper selection of those agents suitable for the various needs in surgical practice it is necessary to understand the chemical, physical, and biologic properties of the substances available. Laboratory tests have been developed to screen lethal tissue poisons from those wherein low toxicity warrants further study.

A number of factors are involved in antibacterial action. The potency of an antiseptic is usually expressed as its *phenol coefficient* which is obtained by dividing the maximum inhibitory dilution of the unknown by that of phenol. Information as to the minimum concentration at which an antiseptic will act in vitro is of value as that it serves as a guide for the selection of a concentration to be used in wounds. If a concentration greater than this minimum found effective in vitro is tolerated by the tissues the antiseptic may be successful. Other factors enter the picture e. g., dilution by tissue fluids. Thus, phenolic compounds are greatly affected by dilution in their germicidal activity whereas the mercurials and the dyes are only gradually reduced in their activity by progressive dilution.

Time and concentration are interdependent and it is well known that if the concentration is increased less time is required for germicidal action. There is, however, a considerable variation in the speed of action between various antiseptics. The hypochlorites and peroxide are quite rapid as compared with the heavy metals and the sulfonamides, the latter being quite slow.

The temperature at which an antiseptic or disinfectant is employed is important, in that a high temperature increases the germicidal potency. This is true particularly in the case of the phenols. From the practical standpoint the use of an antiseptic at high temperatures is not feasible since the solution would either burn tissue or rapidly assume body temperature.

The susceptibility to the action of antiseptics in general varies with bacterial species. Spore formers and tubercle bacilli are quite resistant because of their impenetrability. *Streptococcus fecalis*, *Pseudomonas aeruginosa* and other gram-negative organisms possess considerable resistance to many kinds of antiseptics while gonococci and meningococci are easily killed. Many antibacterial agents show striking degrees of selective action on bacteria. For example, penicillin and gentian violet are strongly inhibitory to staphylococci but only poorly active against most gram-negative organisms. Acetic acid, in a concentration hardly affecting most organisms, readily destroys the *Pseudomonas aeruginosa* which is quite resistant to most substances. A knowledge of selective action is imperative in the proper choice of an antibacterial agent for use against a specific organism.

It is well established that exposure of bacteria to sublethal doses of an antibacterial agent often results in the propagation of resistant and mutant forms that become increasingly difficult to kill.

This factor has very important therapeutic implications such as the advisability of adequate dosage in the early stages of treatment and the change to another agent should habituation of the organism be suspected.

Antiseptics almost invariably are of greater value *in vitro* than *in vivo* i. e. in the presence of body fluids or tissues. The organic matter with which the antiseptic comes in contact consists of plasma proteins, blood cells and foreign bodies such as sequestra and necrotic tissue. These in varying degrees, interfere with the antibacterial action. It is highly important to know how a given antiseptic behaves in the presence of such material and whether any appreciable antibacterial effect remains. All known antibacterial agents are toxic in some degree to tissues as well as bacteria but the toxicity for tissue varies greatly. A number of methods have been devised for testing tissue toxicity. Thus we have a determination of minimal lethal doses by intravenous, subcutaneous, and intraperitoneal injection and the effects after application to the conjunctiva of rabbits. These methods establish the general toxicity of an agent according to the route of administration and the effects of absorption on contact with vital tissues. Such information is most essential for drugs to be administered systemically. When the antiseptic is to be used locally the effects on the skin, muscles, connective tissue and blood cells are of primary significance. The cells of these tissues can be studied histologically in experimental wounds or by tissue culture and the action on leucocytes determined by direct study in the presence of the antiseptic. The relative vulnerability of fibroblasts in tissues is unknown and it is not established that the behavior of one type of cell can be assumed to be similar to that of another type. Howes (34) has devised a very appropriate test for the determination of wound healing following the application of an antiseptic to similar wounds. By serial photographs he establishes the effect on the rate of epithelization in terms of change in the perimeter of an island of epithelium and the effect on the growth of the surrounding granulation tissue. Only by such data is it possible to evaluate accurately the relative toxicity of antiseptics unless they produce gross and immediate toxic effects.

The choice of the mode of application of an antiseptic introduces two problems first how can it be applied to an area so as to exert maximum results and second how can the substance be maintained in the area long enough to achieve the desired results. Aqueous solutions as a rule provide maximum antibacterial action but in such

form solutions intended for the preoperative preparation of the skin require a long time to dry. The use of alcohol as a vehicle produces more rapid evaporation and drying but otherwise it has little advantage. The case of phenol is interesting and it demonstrates the importance of the base or vehicle employed. Aqueous solutions containing 5 per cent phenol are highly toxic to tissues but the same concentration in petrolatum is bland and nonirritating to wounds. Yet because of the greater affinity of the phenol for petrolatum than for water it is released so poorly from the base that the ointment is inert (52). Generally speaking any vehicle other than water causes some loss in antiseptic power although it may be used to secure greater solubility reduce toxicity or in some way to facilitate application. For immediate rapid effects, an isotonic aqueous solution is preferable but for a more prolonged action a number of bases is recommended for example a carbowax water-soluble base¹ a vanishing cream type base² or a lanolin type base³. To compensate for the slow release of antiseptics from these bases somewhat higher concentrations of the antiseptic must be included than is necessary in aqueous solution. Comparative data are needed to quantitatively express the rate of release of antiseptic from different vehicles in comparison with water (33 36 52).

From these considerations it will be seen that the "ideal" antibacterial agent has not been perfected. Although many compounds are antiseptic *in vitro* each lacks some specific function or property that removes it from the ideal category. Thus, one compound may be outstanding in speed of action while another may have outstanding penetrating power. For the complete evaluation of an antiseptic a multitude of tests is necessary and the results must be carefully considered. It must be determined what concentration can be used, how this is to be maintained and over what period of time the antiseptic must remain in the wound. Other considerations are the changes produced in the bacterial flora of the wound the antiseptic's action on tissue repair (whether it is severely inhibited by organic matter) and the possibility of the production of drug resistance. Esthetic considerations such as staining color and odor may be important (26). It is the stain produced by dyes which makes the use of these compounds unpopular.

¹Carbowax is trade name for mixture of polyglycols. An excellent base may be prepared as follows: carbowax (4000) 5 parts, propylene glycol 55 parts.

²A base of this type recommended by Jenkins may be made as follows: oil phase petrolatum 45, Aflac 10, aqueous phase (100 cc) 50, water 50 cc, 50 cc. Aflacil Cream Tissue 50 may be purchased. An excellent lanolin type base can be obtained in the market.

These many variables are difficult to control and often data on each are not available. It is consequently not always possible to establish or state definitely that one agent is superior to another. Manufacturers, by stressing some one point of superiority such as phenol coefficient or low toxicity have introduced an enormous number of antiseptics on the market. It is apparent that some are superior to others and a clinical therapeutic test is undoubtedly the best criterion for selection, provided that one's observations are complete and on a significant number of cases. One should also keep in mind the many variables which make up any group of like surgical cases as pointed out by Meleney (46)

NEED FOR ANTISEPTICS AND DISINFECTANTS IN SURGERY

Every surgical procedure requires some measure of disinfection and antiseptics to convert the nonideal conditions to as near ideal as possible. Specifically one tries to prevent the irreversible damage that is associated with the implantation of bacteria with resulting infection and to minimize the damage that ensues once infection has occurred. The surgeon should keep the following points in mind

1. The oral cavity should receive preoperative preparation when oral sepsis is present to minimize the risk of respiratory disease after inhalation anesthesia.

2. The micro-organisms in the gastrointestinal tract should be destroyed or inhibited so that abdominal procedures will entail less risk of infection.

3. Infections of the lungs and urinary tract should be prevented or controlled when incident to or following surgery.

4. Wounds accidentally produced require prophylaxis. These are all contaminated and therefore potentially infected (354). Such wounds often occur when ideal surgery is impossible because of such factors as time, geographical situation, or anatomical nature of the wound. The need for antiseptics is increased under conditions of war as adjuvants to fundamental surgical steps such as debridement, control of hemorrhage, and drainage.

5. Wounds in which bacteria have already gained a foothold and are producing an inflammatory process require appropriate treatment.

6. Methods for the destruction or inhibition of organisms which have traveled from a portal of entry by the blood or lymphatic systems to other parts of the body (generalized infection) should be instituted immediately.

7. All sutures, tubes, drains, powders, and solutions should be sterilized and all organisms contaminating knife blades, scissors, needles, and the like should be destroyed.

8. Air in operating rooms should be sterilized and cross infection eliminated in wards.

9. The micro-organisms on the hands and arms of the surgeon as well as on the skin of the patient at the site of operation should be destroyed.

10. Contamination of gloves or hands after contact with infected material such as dressings should not be overlooked and when it occurs disinfection instituted.

THOSE AGENTS PRODUCING DISINFECTION BY PHYSICAL MEANS

Dry heat or hot air. Th. Paul has shown that bacteria dried at various temperatures, according to the organism, die partly as the result of an oxidation reaction. Desiccation is also partially responsible. Glassware and instruments which are not affected by loss of temper may be conveniently sterilized by dry heat. This is of value particularly when they should be dry in order to be stored for future use. Powders such as talcum, zinc peroxide, the sulfonamides, and others which possess a tendency to cake on contact with water, oils, and ointment bases may be sterilized by hot air at a temperature of 140° C. or over in order to destroy spores. The temperature is dependent upon the compound since too high temperatures will decompose some substances. A temperature too much above 160° C. will char cotton plugs and covers. A temperature of 140° C. for 4 hours for zinc peroxide and the carbowaxes has been found satisfactory (38). For the sulfonamides from 145° to 150° C. for 4 hours is sufficient. Six hours at 140° C. are frequently necessary for petrolatum or mineral oil which act as protectives to the bacteria.

Moist heat. Moist heat sterilizes or kills bacteria by a completely different mechanism than does dry heat. The protein of the bacteria is coagulated by moist heat which leads to quicker destruction. In the case of moist heat the thermal death points of the bacteria also vary. Spores of certain bacilli and clostridia are exceedingly resistant and may live through 110° C. and 130° C. for 20 minutes. In such cases it is necessary to heat for a longer period of time. This applies to the boiling of instruments in water or the sterilizing of linens in a steam autoclave. In an autoclave the objects being processed become water soaked but they can be dried by producing a partial vacuum as soon as the autoclaving process is finished. Ointment bases such as the carbo-

waxes act as protectives to the bacteria against moisture. In such cases the spores are not destroyed by steam sterilization.

Ultraviolet light Ultraviolet radiation does not effect complete sterilization but rather a reduction in the total number of bacteria present. The radiations which destroy the bacteria are found in the spectrum from 2 000 to 2 950 Angstrom units and Finsen first treated skin tuberculosis with such ultraviolet radiation. These radiations destroy both pathogenic organisms and those causing decomposition and putrefaction (27) and they are particularly valuable in operating rooms where the effect is rapid. The incidence of operative and postoperative infection can be reduced by 50 per cent with the use of ultraviolet lamps. Cubicles for the handling of septic cases, nurseries, children's wards, and similar departments may also employ ultraviolet radiation. Unfortunately protection against the erythema producing effect on the eyes and skin is necessary.

ANTISEPTICS ACTING PRIMARILY BY CHEMICAL ACTIVITY (THE SURFACE ANTISEPTICS)

Acids and Alkalies It has been determined experimentally that the maintenance of pH below 5 or above 9 for a specified period of time will allow for the establishment of a state of antiseptis (1). Except in the urinary tract the maintenance of such pH states is difficult, partly because of the powerful buffering and neutralizing action of the tissues and fluids. In the urinary tract it is possible to maintain certain conditions of pH without harm to the epithelial lining. This is accomplished by the administration of mandelates, phosphates, ammonium chloride and similar substances. Mandelic acid is an effective urinary antiseptic.

The antiseptic activity of many acids is directly proportional to the hydrogen ion concentration which they produce in aqueous solution. This is true also of alkalies in that their activity is directly dependent upon the number of hydroxyl ions which are produced. The theory has been advanced that acids and alkalies neutralize the free basic or acidic portions of protein and consequently destroy the bacterial organisms. Some acids exert their bactericidal effects because of the undissociated molecules. Among these are included acetic, lactic, benzoic, salicylic, and mandelic acids.

The strong mineral acids which dissociate readily are not practical because of the fact that they irritate the skin and mucous membranes and are too caustic. Boric acid has been employed for years as a relatively nonirritating although weak germicide for the eyes and for burns. It is a cumulative poison when applied to extensive raw

surfaces and since its antiseptic action is doubtful, other agents would be more efficient (50). Superficial dog bites are sometimes cauterized with nitric acid although some believe it valueless since the rabies virus spreads so rapidly.

The organic acids are much less dissociated and therefore less powerful than the inorganic or mineral acids. Superficial *Pseudomonas aeruginosa* infections are destroyed with weak solutions of acetic, lactic, or propionic acids, preferably in buffered solutions. These acids are also fungicidal. Buffered solutions of these acids are preferable in order to prolong the time of activity as well as their effectiveness. Experiments in vitro have shown that a weak solution of acetic acid requires from 10 to 15 minutes to destroy cultures of the *Pseudomonas aeruginosa*. Thus it is clear that a vehicle is necessary to maintain the agent in longer contact and to inhibit neutralization by tissue fluids. A carbowax base containing 3 per cent acetic acid and 4 per cent sodium acetate is less irritating and possesses a more prolonged action than a 3 per cent solution of the acid alone (53).

It has been stated previously that maintenance of a high degree of alkalinity (above a pH of 9) is not conducive to the life of bacteria. Alkalies possess a solvent action in dissolving proteins and saponifying fats which property is of value in wounds if the agent is continuously applied. The Carrel Dakin hypochlorite treatment is typical of this technique (9). Caution must be observed in such technique since too great an alkalinity is irritating and corrosive to the skin and other tissues (48). Repeated application of mild acids has been found less harmful in animal wounds than that of mild alkalies (35).

Alcohols Absolute and 95 per cent strengths of ethyl alcohol are relatively ineffective. The greatest bactericidal power is obtained with a concentration of 70 per cent by weight. The activity is diminished considerably if this is varied (48). In 70 per cent strength only the less resistant bacteria are killed. The property of coagulating proteins which ethyl alcohol possesses, in turn makes it locally toxic to tissues. Consequently bacteria may be protected from its effect. Chloroform and ether will do the same. This coagulation of protein probably is the cause for the decrease in efficiency of other antiseptics when alcohol is employed as the solvent (4). Thus alcohol is not to be recommended in cleansing wounds of bacteria dirt and greases. Experimental work has revealed that spores survive indefinitely in the presence of ethyl alcohol (38). Alcohol is commonly used to sterilize rubber caps of vials but when sporebearing dust has accumulated such an

and emulsifying action. In antibacterial activity they are comparable to tincture of iodine. The concentrations necessary for an antibacterial effect are relatively nonirritating. In one respect the surface activity of the cationics is a disadvantage. In repeated applications to wounds they disrupt tissue elements, and cause hemolysis, and their antiseptic strength is diminished by the protein present. The cationic detergents also are not very effective against spores (48). Surgical instruments may be sterilized and these detergents used for storage of sterilized instruments, provided their ineffectiveness against spores is kept in mind. Corrosion is prevented by the addition of 0.5 per cent of sodium nitrite.

Halogens. No two chemicals possess as well known a reputation for active germicidal action as do chlorine and iodine. Their reaction to form combinations with the protein amine groups is responsible for their antibacterial activity. Continual application or constant renewal of applications is necessary since proteins rapidly inactivate them. The hypochlorite solution commonly known as Dakin's solution is usually employed in place of chlorine. As previously mentioned the alkalinity of the hypochlorite solutions is an additional advantage. As a result of the alkalinity they possess a destructive and solvent action on bacteria, pus, necrotic tissue, silk and catgut. The well known Carrel-Dakin technique (9) of irrigation meets the necessary prerequisites of constant renewal. The disadvantages of this treatment are several.

1. Irrigations must be constantly renewed, special apparatus is necessary and the daily change of dressings, even if painlessly accomplished predisposes to recontamination of the wound from outside sources.

2. The surrounding skin must be protected (by petrolatum gauze) or bothersome irritations will occur.

3. An alkalinity of pH 10 must be maintained by buffers, because tissue irritation is marked on either side of this range. Thus, the solution must be made daily and kept in dark bottles, because of its photolability. (The U.S.P. preparation is a buffered solution).

The next compounds to be considered namely chloramine T, dichloramine T and azochloramid, act more slowly and combine with organic matter less rapidly but their activity is more prolonged, particularly when serum proteins are present. Unfortunately they do not possess the effect on slough that Dakin's solution does (24). They are more stable but are photolabile and must be stored in amber bottles. The problem of azo-

chloramid in relation to wound healing was studied carefully by Anderson. Single applications for several days caused a reduction of the bacterial flora in granulating wounds but not in sloughing wounds. Healing time was not influenced in either type. In *in vitro* studies, azochloramid possesses a synergistic action with the sulfonamides but no proof has been advanced of the synergism in the body.

Iodine has had a wide reputation as an efficient germicide. It is commonly used in the form of the tincture and is one of the most reliable agents for preoperative skin preparation. The chief advantage of the tincture is the rapid drying brought about by evaporation of the alcohol. Although the tincture has been so widely used the aqueous solutions of iodine are gaining in prominence and more reports appear on their highly germicidal action. Lugol's solution U.S.P. is a 1:6.4 dilution has been shown by Nye (49) to be active *in vitro*. For preoperative skin preparation the aqueous solutions possess certain advantages. Kraissl and Melency compared certain aqueous preparations (ethioline, tetrodine) with tincture of iodine, U.S.P. on guinea pigs. The addition of certain surface active agents to these aqueous preparations causes them to spread, penetrate and dry more quickly than Lugol's solution. Where the tissues are abraded there is no stinging sensation as with the alcoholic preparations. The use of aqueous iodine preparations has been slow as a result of a necessity to choose between proprietary preparations.

There are available certain organic iodine compounds (chinkofon, vioform, dilodoquine) which possess no antiseptic value in their use as dusting powders on wound surfaces. Extremely low solubility is the responsible factor. Their use is limited mainly to that of anesthetic (36, 48). The penetrating odor of iodoform has long been associated with antiseptics. However its solubility in water or serum is so slight that it is practically inert. No confirmation has been presented that iodine is liberated by iodoform in contact with tissues. Thymol iodide (aristol) possesses no value as a local antiseptic for its solubility in water is still less.

Heavy metal salts and compounds

Mercury. Cells contain sulfhydryl (SH) groups which are coagulated by inorganic mercury salts to form mercury proteinates. Functional enzyme systems are inactivated and deprived of nutritional support by the compound formed. The reaction is reversible and under optimum conditions the proteinate is dissolved and the bacteria are free to resume normal activities. The bacterio-

static action of the mercurials therefore is diminished considerably by the presence of skin blood and wound exudates which contain sulfides and sulphydryl groups. In addition the simple mercuric compounds are irritating and toxic and not safe for use in wounds. Mercuric chloride solutions which are acid in reaction are very slow in their antibacterial action. This coupled to the fact that a small quantity of soap inactivates a whole basin of the solution is a drawback to their use as hand rinses. Sterilization of instruments with these compounds is precluded because of their corrosive action. In the disinfection and storage of mechanically clean catheters, bougies, filiforms, and similar instruments when there is no danger of spore contamination a 1:1000 solution of mercury oxycyanide is used. The germicidal activity of soaps has been increased by the incorporation of alkaline potassium mercuric iodide. The flora of the skin is not appreciably reduced by this compound or mercuric chloride but strangely a sterile cutaneous surface may be produced. Price explains this as being due to the transparent film on the skin under which the bacteria are confined. Multiplication occurs under this film. The bacterial flora present doubles every 30 minutes. Sweating breaks the film and the uninjured bacteria are released.

Merthiolate, a complex organic mercurial and metaphen, a phenyl mercuric compound and related agents do not take a very clear position. They do not liberate readily inorganic mercuric ions, but they possess cations of high molecular weight which opens the possibility of their behavior as cationic antiseptics. Compared with the simple mercury compounds their potency is much greater and their toxicity and irritating power are considerably less. In the presence of serum proteins they retain a fair proportion of their activity but blood and pus inhibit their activity to some extent. They are not suitable for wounds and are not as efficient as is commonly believed for the disinfection of instruments (6). As preoperative skin disinfectants they are widely used. Their slow action (slower than iodine) and their lack of sporicidal action are disadvantages. Johnson (37) has found that merthiolate is unreliable as a preservative for stored liquid plasma.

Silver and silver foil. Metallic silver is bactericidal and is economically practical in the sterilization of water. Very little evidence has been accumulated in favor of the insertion of silver foil into wounds as an application of the principle of oligodynamic action of metals. A compound of silver namely the nitrate, is employed in surgery mainly for canterization. It is also of use in trim-

ming of granulation tissue and warts. Corrosion, astringency, pain and irritation accompany its application. Silver nitrate formerly was used with tannic acid in the treatment of burns. This has been discontinued because it increases the depth of the burn, masks cellulitis and infection and delays wound healing and early skin grafting. Colloidal silver compounds provide antiseptic by the release of very low concentrations of silver ions. In addition they are noncorrosive and relatively nonirritant. These compounds are employed mainly on mucous membranes. Argyria, an irremediable discoloration of the skin or mucous membrane may occur as a result of the use of silver for a long period of time. Solutions of silver should be freshly prepared as they are photolabile.

Bismuth. Mechanical protection of inflamed or irritated surfaces is provided by the insoluble bismuth compounds. Antiseptic action is possessed by certain combinations of phenols and bismuth salts in which the hydrogen in the benzene ring has been replaced by bromine or iodine such as bismuth tribromphenate (xeroform). This compound is recommended by plastic surgeons to cover areas of skin grafts and donor sites (66). No delay in wound healing has been observed under this dressing. Xeroform is applied in ointment form for which the formula is bismuth tribromphenate 3, petrolatum 95, paraffin 1, beeswax 1. Several layers of narrow mesh gauze in a rectangular tin box are impregnated with the ointment and the whole sterilized in the oven at 140° C for 4 hours.

Oxidizing agents. The oxidizing agents act against bacteria by oxidation of the protoplasmic constituents. Included in this group are ozone, the permanganates and peroxides. Agents of this type are particularly effective against anaerobic organisms which are inhibited by a high concentration of oxygen. Proteins inactivate these oxidants and no distinction is made between those of bacteria and of tissues. They must be constantly renewed in order to sterilize unless the effect is instantaneous. Zinc peroxide (U.S.P. medicinal grade) recently introduced, is the only peroxide which has prolonged action.

The powder may be employed as a 40 per cent cream made with sterile water or a 20 per cent ointment made with a carbowax base (55). Both must be freshly prepared. In these vehicles the zinc peroxide will slowly liberate oxygen in a wound for 24 hours. In vitro tests have shown this chemical to be bactericidal to sporulating anaerobic gram positive bacilli, hemolytic streptococci and pneumococci, anaerobic cocci

and bacilli, but not to the staphylococcus or most aerobic gram-negative rods. Many uses have been developed for zinc peroxide in surgery among which are included the following: (1) orally as a mouth rinse and gargle, in Vincent's angina and pyorrhea alveolaris; (2) topically on foul smelling indolent wounds such as ulcerated cervical cancers which are covered by sloughs and produced by gram negative anaerobic nonspore-forming bacilli such as the *Bacillus furiformis* and the *Bacillus necrophorus*; (3) in conjunction with excision and wide exposure for control of the chronic indolent burrowing ulcers caused by a microaerophilic hemolytic streptococcus; (4) in conjunction with excision of devitalized tissues and wide exposure for control of the spread of bacterial synergistic skin gangrene caused by the symbiosis of two or more organisms; (5) in empyema after evacuation and rib resection when anaerobic mouth organisms are located on the remaining fibrin and adherent slough; (6) around colostomies as a dressing in the perineum after prostatectomies and resections, and in the anal canal after hemorrhoidectomies and fistulectomies; (8) Zinc peroxide does not reach the deep and widespread infiltration of the infection therefore it does not have a material influence on gas gangrene unless the exposure is adequate. Zinc peroxide decomposes into zinc oxide and hydroxide which remain in the wound and provide a disadvantage. In rectal cases their astringency is advantageous. The vehicles in which zinc peroxide is suspended are absorbed or washed away by exudates which causes the chemical to dry. Therefore, the wounds should be protected by layers of water-saturated cotton and several thicknesses of petrolatum or zinc oxide ointment gauze. Although hydrogen peroxide is a weak antiseptic it does have some value in surgery as an aid in releasing sticky exudate-soaked dressings, cleansing surface wounds and like conditions. A mixture of hydrogen peroxide with tincture of green soap is useful in removing crusts and dried wound exudates. The concentrations necessary for potassium permanganate to be effective are irritating and therefore it is no longer recommended.

Phenols and phenolic derivatives. Phenol is the simplest of this group of antiseptics. It is soluble to the extent of approximately 6 per cent in water. Because of its great destructiveness to tissues, its use in surgery is limited chiefly to opening furuncles by allowing the phenol on a needle or toothpick to puncture the center of the furuncle and simultaneously seal off the capillaries (bloodless technique). Although more bactericidal and

less toxic, the higher phenolic derivatives are less soluble in water. The cresols, of which lysol is a mixture of ortho-, meta- and para-cresol is best known, must be dissolved by means of soap in order to be effective. Lysol is three times more bactericidal than phenol and slightly less toxic, but its caustic property renders it unfit for wound or skin applications. Lysol is chiefly used for the disinfection of contaminated utensils and the scrubbing of walls, floors, and bath tubs. Cresols, unfortunately, are not sporicidal and not very soluble in water; they possess a strong and persistent odor and lose germicidal activity when mixed with too much soap. Hexylresorcinol, rejected by the Council of Pharmacy and Chemistry in 1936 as an antiseptic for the N. N. R. but official in the U. S. P. as an anthelmintic, is highly bactericidal under optimal conditions. It is irritating to tissue and its activity is diminished by organic matter. Thymol is fungicidal and has produced varying results in the treatment of actinomycosis, blastomycosis, monilliasis, and pyoderma granuloma. Trinitrophenol, commonly known as picric acid, is not so widely used as a burn dressing and for preoperative preparation of the skin as formerly because of the fact that it is a systemic poison and occasionally causes a severe local dermatitis. A valuable disinfectant with low toxicity for use on inanimate objects is a combination of certain synthetic alkyl and aryl phenolic derivatives known as amphyl. Moderate amounts of organic matter do not deactivate it. Pulaski and Meleney (53) found p-chlorophenol to be most effective against *Haemodromas seruginosa* and *Proteus vulgaris* in dilutions of from 1:3,000 to 1:5,000 both *in vitro* and also in the control of superficial and adequately exposed wounds infected with these organisms. A concentration of 0.25 per cent in carbowax base applied once daily is recommended.

COMMENT

The many antiseptics that have been presented represent the continued efforts throughout the years to improve surgical antisepsis. Their acknowledged failure as "all-purpose antiseptics" has resulted in widespread pessimism concerning their utility in practice. Two quite opposite trends have developed: first, there are new antiseptics constantly being introduced and used; second, a trend has developed which might be termed antiseptic nihilism. It discredits all antiseptics for use in wounds and recommends the use of agents to stimulate the normal mechanisms of the body in combating the infective process. According to this school of thought only heat and

salt solutions (lymphagogues) should be used such as sodium chloride sodium sulfate and magnesium sulfate

Is it not too much to ask that all the requirements of the all purpose antiseptic be met by a single substance? It is certain that up to the present no chemical has been discovered which effectively combines all of the properties demanded of a general antiseptic, although a considerable amount of time has been spent in search of it, at present the all purpose antiseptic appears to be an impossibility

For many years clinicians and investigators have had a fixed idea concerning a general purpose antiseptic and this idea has been perpetuated by pharmaceutical houses in their advertising. The term itself suggests that there are substances effectively antibacterial against all forms but still sparing the body tissues. Such generalities should be succeeded by the choice of specific substances which perform the best for a specific requirement, which is in essence the concept of chemotherapy. By such means one selects agents having a much greater affinity for the bacteria present than for the tissues of the host so that the micro-organisms can be overwhelmed at minimal expense to the surrounding tissues. It has been pointed out how certain agents can be used with maximum advantage against certain organisms, i.e., they are chemotherapeutic, while others are so damaging to tissue that they can only be used on nonliving matter

The 'physiological school' also falls into similar errors as those who believe in an 'all purpose antiseptic' by limiting therapy to heat and saline solutions, whether passive (isotonic) or active (hypertonic). Although the use of hypertonic salt solutions can hardly be called physiological, both methods commit the same error in disregarding the bacterial flora of the wounds. In their place these methods, like a given antiseptic have value but not universally so

ANTISEPTICS WHICH ACT BY INTERFERING WITH A SPECIFIC FUNCTION OF THE BACTERIUM (SULFONAMIDES AND ANTIBIOTICS)

In previous sections those agents which act as antiseptics when locally applied have been discussed. In this section will be discussed those agents which control infection by what might be called systemic chemotherapy. There are many more possibilities for the use of agents of this type than for the others. Chemotherapy by means of the circulation began centuries ago with the treatment of syphilis by mercurial inunction. It has progressed through the ages to the sulfona-

mides and antibiotics for treatment of bacterial infections.

Ehrlich and Shiga in 1904 used trypan red a synthetic dyestuff to cure an acutely fatal general infection in mice due to trypanosomes. Quinine was the only substance ever used before in an analogous manner. Behring's successful use of antitoxin in diphtheria was valuable but serotherapy still did not furnish a universal method of treating bacterial diseases. This coupled with the fact that a synthetic organic compound had cured a protozoan infection furnished the incentive for research. Examination was made of the aniline dyes. Gentian or crystal violet was shown by Churchman to have powerful antibacterial action. Morganroth and his associates reported that optochin (an alkaloid of the quinine group) had cured mice whose blood was infected with virulent pneumococci. In the untreated controls a rapidly fatal septicemia occurred. No similar effects had been achieved with any other drugs or organisms in other animals. Antisera, antitoxins, and bacteriophages were introduced but the situation was still not very hopeful.

A Sulfonamide (60) Domagk in 1935 announced that hemolytic streptococcal sepsis in human beings as well as in mice could be controlled by treatment with certain azo dyes. No announcement of any chemotherapeutic agent was ever so startling or so immediately effective in saving many lives. Sulfanilamide was discovered to be the active part of the dye molecule. The new age of chemotherapy which this discovery heralded has led to more fundamental progress in antiseptics as well as to the solution of many problems of therapy. The search for new agents has become more rationalized. The sulfonamides act systemically by confining their action to a specific function of the bacterium rather than by exerting a universal chemical effect such as that employed by the antiseptics discussed in previous sections.

As a result of certain inherent characteristics information on the sulfonamides was rapidly accumulated. Inexpensive manufacture and general use resulted from their comparative chemical simplicity and feasibility of synthesis. This latter factor showed the way for the preparation of many derivatives of the original compound. In vitro study is possible since the sulfonamides do not require the natural defenses of the body for their effect. Not only do they dissociate as acids but the presence of an amino group which can be rapidly diazotized allows for accurate and fairly simple colorimetric tests of concentration in the body fluids. Thus, the calculation of therapeutic

levels is expedited. The mode of action of the sulfonamides is much less definite than are their therapeutic properties and their limitations due to toxicity and ineffectiveness against certain types of organisms. The discovery (67) that p-aminobenzoic acid neutralized the effect of sulfonamides on hemolytic streptococci in vitro and in vivo led to the conclusion that these drugs must displace or block the utilization of an essential metabolite, probably p-aminobenzoic acid from a bacterial enzyme. With this enzyme system no longer able to function the organisms could not utilize food material and were unable to survive. Thus, the fact that the sulfonamides attack a specific function of bacteria was established. This was one of the first successful attempts in the establishment of antiseptics by this method and proved of great biological interest (13).

Phagocytosis has always been an important factor in eliminating infectious organisms from the body. The sulfonamides allow the host to act against the organisms, which is a secondary factor in their activity.

Unfortunately there are substances of importance to the surgeon which also inhibit sulfonamides. Procaine and other related local anesthetics are esters of p-aminobenzoic acid. When injected they decompose into the parent compound. Inhibiting substances are also present in peptones, pus, and necrotic tissue.

Bacteriological diagnosis, proved efficacy, pharmacological properties, and toxic reactions (variety, frequency, and severity) are the factors to be considered by the surgeon in choosing a sulfonamide compound for control of surgical infections. Sulfadiazine is the best drug for infections caused by the hemolytic streptococcus, pneumococcus, meningococcus, Friedlander's bacillus, and also for *Bacillus coli* and other sulfonamide sensitive urinary tract infections. In gonococcal infections, sulfathiazole is preferable. Sulfasuxidine takes precedence in bacillary dysentery and in preoperative reduction of the gram-negative flora of the intestine. Hemolytic *Staphylococcus aureus*, the enterococcus, and the viridans group of streptococci are comparatively unaffected by sulfanilamide and sulfapyridine. Sulfonamide therapy is ineffective against anaerobic and microaerophilic hemolytic streptococcus infections irrespective of location. Gas gangrene is not prevented nor is its course influenced by the sulfonamides. They are of little value in brucella, pasteurella, and hemophilus (influenzae) infections.

The local treatment of some bacterial infections by means of crystalline sulfonamides has attained widespread use following the report of control of

infection in compound fractures by Jensen, Jarud, and Johnson. Colebrook found sulfanilamide valuable when applied topically to superficial open hemolytic streptococcal infections. As a result of lay publicity on the control of infections in war wounds, the sulfonamides are enjoying popularity as general purpose antiseptics. The local use of sulfonamides has been carefully reinvestigated. When used to greater extent than a dusting of soluble sulfanilamide they may cause irritation, produce exudate, delay healing and promote the formation of adhesions. Inhibitory necrotic tissue and pus is pronounced. Rapid absorption and toxic blood levels result from the application of more than 10 gm. over extensively wounded or burned areas in a 24 hour period. When continuously applied to intact skin for more than 5 days sensitization may occur. This is exceedingly dangerous since it may prevent the use of the sulfonamides later in an infection where which no other drug is effective. The focus are serving to reduce the local use of sulfonamides for wound antiseptics. It is now felt that local use of sulfonamides in wounds has no advantage over systemic administration of the drugs.

DRUG RESISTANT INFECTIONS

There has been observed in a certain proportion of cases of pneumonia, wounds, burns, meningitis, and gonorrhea that the sulfonamides do not control the infection. Worthy of particular mention are those refractory cases which obviously have the same species of causal organism and clinical features as the responsive ones. Such organisms are believed to be drug-resistant. The infection first is affected by the drug but before it can be controlled the organisms develop resistance. The resistant bacteria in turn propagate resistant bacteria. They still retain their virulence. Variance in defense by the host also plays part but this cannot be measured readily. In vitro testing of the responses of each patient's strain of organisms to sulfonamides has been developed into a simple technique (25). With this test accurate prognosis of the results can be made and the period of time wasted before recognition that other forms of therapy are necessary is decreased. This in vitro testing promises much for the future for in some infections (fulminating) life is dependent upon the early use of the proper drug.

B. Substances of Biologic Origin

Nature is a treasure of antibacterial agents. Quinine, emetine, chaulmoogra oil, tannic acid, and many others are plant products. Even cabbage onion, barberry plants, and others have

provided extracts which possess bacteriostatic agents. Chlorophyll has been found of promise in the acceleration of wound healing (59). Many of these substances require further investigation. Selective antibacterial properties are found in substances contained in tissues and body fluids.

Toxins, antitoxins, and immune sera come from animals. The prophylaxis of gas gangrene with such products is not as clear-cut as immunization in diphtheria and tetanus. The specific antibody still retains an important position in the prophylaxis and treatment of bacterial infections. In infections of the gas gangrene and *Clostridia* tetani group bacteria are so actively toxigenic that penicillin and the sulfonamides have very little direct neutralizing effect upon the toxin.

1. **Antibiotics.** Bacteria and fungi recently have attained great prominence as sources of chemotherapeutic agents. Seven groups of microbial products produced from an amazingly large variety of unrelated micro-organisms have been listed by Waksman (64). Included in this listing are polypeptides such as tyrothricin, pigments such as pyocyanin (alphaoxyphenazine) lipoids, such as pyocyanase, organic bases such as streptothricin, simple organic molecules such as hydrogen peroxide and others, such as penicillin. In general, the antibiotics are toxic to animal tissues just as are the synthetic chemical compounds. Many antibiotics have been isolated but only the following 4 show therapeutic promise: tyrothricin, penicillin, streptothricin, and streptomycin. The N.R.R. has approved the first 3. The use of pyocyanase in the local treatment of infections has been discontinued or limited due to its instability, variability of organisms from which it was derived, and lack of information on the conditions controlling its formation.

a. **Tyrothricin.** Dubos (17) in 1931 first extracted tyrothricin from cultures of *Bacillus brevis*, a gram-positive, aerobic, sporeforming soil organism. To this worker should go the credit for renewing the interest in antibiotics. Tyrothricin is a protein (polypeptide) and a hemolytic agent which makes it dangerous if given intravenously. It is ineffective intravenously and orally as well. It consists of at least two substances, gramicidin and tyrocidin. Gramicidin is more active and although hemolytic, is relatively nontoxic for other tissue cells. Several species of gram-positive organisms such as pneumococci, streptococci and staphylococci are susceptible to its action. It is of value in mastoiditis, burns, empyema, superficial ulcers, and similar conditions in which direct contact locally can be ac-

complished. Its limited penetrating powers restrict its use in deep seated infections. Tyrothricin inhibits enzymatic action in the bacteria causing a retardation of growth and lysis of the cells. Saliva, urine, and serum do not inhibit it to any degree. It is greatly inhibited by gram negative bacilli which in mixed infections may even protect the sensitive gram positive bacteria.

b. **Penicillin.** Penicillin is a solid substance extracted from broth cultures of the mold *Penicillium notatum*. The sodium and calcium salts are the forms principally used. Fleming discovered the presence of penicillin in 1929 but it was not applied clinically until Chain and others produced it in sufficient quantity.

Penicillin is a yellowish brown powder and is marketed in sealed ampules. It is unstable in air, hygroscopic, and loses potency rapidly when exposed to heat, alkalis, acids, primary alcohols and oxidizing agents such as hydrogen peroxide. Crystalline sodium penicillin just recently released, is much more stable and can be stored at ordinary temperatures without refrigeration. It is believed that some of the impurities which cause reactions in some patients have been eliminated in this product. Penicillin is extremely soluble in water and saline and dextrose solutions. The potency of penicillin preparations is measured by comparing them with a standard using either the serial dilution method or a modified agar cup technique and a standard strain of organisms.

In penicillin therapy it is necessary to know the infecting organism. Gram-positive cocci and bacilli, spirochetes, gonococci and meningococci are very susceptible but gram negative bacilli and acid fast bacilli are resistant. Enzymes (penicillinases) produced by gram negative bacilli and by certain aerobic, gram-positive sporebearing bacilli such as the *Bacillus subtilis* group inactivate penicillin. It is also rapidly inactivated by certain strains of resistant micrococci. Infections due to pure cultures of susceptible organisms are considerably more affected by penicillin than are those due to mixtures of gram-negative and gram-positive organisms. Penicillin is the least toxic of all known antibacterial substances. Reference was made to resistant strains and acquired resistance under the sulfonamide drugs. These factors are also prevalent in penicillin therapy but to a lesser degree.

Penicillin possesses certain advantages over the sulfonamides. It is less toxic and therefore there is no tendency to cause the side effects observed with the sulfonamides. Large numbers of bacteria, blood, pus, peptones, or necrotic tissue products do not inhibit it when applied locally.

In local administration it tends to diminish the exudate rather than increase it. Drug fastness or resistance is less frequently observed. Unfortunately, it possesses specificity of action, is inhibited by gram-negative bacilli and is rapidly absorbed and excreted, which makes frequent dosage necessary. Instability was initially a disadvantage but this has been diminished to a considerable extent.

Oral administration of penicillin in conjunction with alkalies and other compounds has been accomplished and provides a simpler method of maintaining bacteriostatic levels (18). By the oral route several times the parenteral dosage is required to maintain adequate blood levels.

Penicillin is also administered locally or systemically. Parenteral administration for common infections requires a dosage of 100,000 or more units daily, divided into 3-hour doses. For topical solutions or ointments containing 500 to 5,000 units per gram are recommended. Daily instillation of from 10,000 to 20,000 units diluted in from 5 to 10 c.c. of spinal fluid or in 10 c.c. of isotonic saline solution is the average dose by intrathecal administration. Two or three times this dosage and volume are necessary for intrathoracic instillation. Peanut oil or oil and wax suspensions of the penicillin are used to slow absorption on intramuscular injection. For topical application, penicillin powder with dry plasma, or incorporated into an ointment base such as carbowax or purified lanolin, provides a preparation from which the medication is slowly released.

Claviformin clavacin, penicillic acid pyocyanin, fumigatin streptothricin and streptomycin are also antibiotic agents which have been developed with a view to finding an agent which is less specific. Streptothricin and streptomycin are the only 2 which have shown clinical possibilities.

c. Streptothricin. This substance is obtained from *Actinomyces lavendulae*. It showed promise in the early days in the local treatment of infected wounds and burns and in those infections produced by dysentery and *Salmonella* organisms (gram-negative bacterial infections). Its activity is not influenced by blood, serum, peptone, or B complex vitamins and is not destroyed by gastric acidity. However it has been more or less overshadowed by streptomycin.

d. Streptomycin (20, 29, 30, 39, 56, 57). This substance was first isolated in 1942 from 2 strains of actinomyces related to *Actinomyces griseus*. It is soluble in water and possesses a selective action against gram-negative bacteria as does streptothricin, but it is considerably less toxic. Strept-

othricin possesses some effect on fungi which streptomycin does not. Experiments with larvae tests and infections in mice have shown that streptomycin is active against a variety of gram-negative and gram-positive bacteria. Streptomycin possesses an effect, therefore, on such gram-negative organisms as the *Eberthella*, *Salmonella*, *Escherichia*, *Shigella*, *Klebsiella*, *Brucella*, *Pasteurella*, and the *Proteus* groups. Considerable resistance is shown by some strains of *Pseudomonas*. Sensitivity to streptomycin is shown by staphylococci, hemolytic streptococci, and pneumococci, whereas resistance is exhibited by all members of the sporebearing anaerobic group. Streptomycin is more effective when administered parenterally. Orally, sufficient dosage will sterilize the gastrointestinal tract of lactose-fermenting organisms. In order to maintain an effective blood level, streptomycin must be injected frequently since it is rapidly excreted by the kidneys. The average daily dose administered intramuscularly is from 1 to 3 million units divided into 3-hour doses. Streptomycin is indicated in tularemia, influenza, and *Klebsiella* pneumoniae infections and as a supplemental aid in peritoneal and urinary tract infections caused by susceptible gram-negative and gram-positive organisms. It has shown some promise in tuberculosis therapy.

Lysosyme (16, 32) a polypeptide, is obtained from tissues and egg white. It destroys a polycyclic structure of susceptible bacteria. It is possible that other enzymes will exhibit valuable properties in surgery not for their antibacterial activity but because they accelerate digestion of necrotic tissue which provides the greatest inhibition to antiseptics. The bacteriophages were introduced long before the sulfonamides and penicillin. They were used in treating *Bacillus coli*, *Bacillus proteus*, *Staphylococcus aureus* infections and bacillary dysentery. Further investigations of these may reveal new possibilities.

It is with these substances which act by interfering with the essential metabolism of certain organisms that the greatest developments of the future must lie.

ABSTRACTS OF CURRENT LITERATURE

SURGERY OF THE HEAD AND NECK

EYE

Hughes, W. L. and Cole J. G.: Technical Uses of Air in Ophthalmology. *Arch. Ophth., Chic.* 1946 35 535.

The author describes the various uses of air in the diagnosis and treatment of various ocular conditions. In surgical procedures air has been found of value in several ways namely (1) in perforating injuries of the cornea (2) anterior synechias after discussion (3) vitreous in contact with the cornea (4) cataract extraction (5) trephination (6) absence of the anterior chamber after cataract extraction trephination, or similar operations and (7) air goniotomy.

A description is given of a new instrument which makes possible the insufflation of air and active treatment of synechias at the same time.

A complete discussion of the author's paper which was read at the Eighty First Annual Meeting of the American Ophthalmological Society (November 12 1945) is included. HUXTER H. ROWLAND, MD

Parker, F. W., Jr.: Studies on Dark Adaptation in Military Personnel Complaining of "Night Blindness." *Arch. Ophth., Chic.* 1946, 35 555

With the use of the Nagel adaptometer the author has investigated the complaints of night blindness in a series of military personnel. The findings are summarized as follows:

Sixty six patients were examined with a Nagel adaptometer for determination of dark adaptation. Careful ophthalmological examinations were made and neuropsychiatric consultation was secured when indicated.

Thirty-nine patients in the group complained of moderate to extreme night blindness. Fourteen had no ocular complaints and 13 were patients with hepatitis.

Of the 14 patients with no ocular complaints, all showed normal adaptation curves, and final readings after a period of 45 minutes ranged from 50,000 to 150,000 Nagel units. None had a corrected central vision of less than 20/30 and with homatropic cycloplegia none had a refractive error of more than 1.00 D.

Of the 39 patients complaining of night blindness, 5 with moderate complaints showed normal dark adaptation and 3 of these had more than -1.50 D. of astigmatism. For 6 others with normal readings but with severe complaints detailed histories revealed some incident that had caused the patient to believe that his night vision was inadequate. Of this group, 3 patients were found to have moderate myopic astigmatism.

The remaining 28 of the 39 patients who complained of night blindness had initial low readings, dark adaptation. No cause for this could be found in 5 patients and these men were considered to have true simple hemeralopia. 4 had a pathological condition of the fundus. 5 patients proved to be malingering and 14 were psychoneurotic.

Of the 19 patients who were malingers or psychoneurotic, 11 had corrected vision of 20/40 or better and 12 had refractive errors of above 1.50 D.

Halk, G. M.: The Management of Intraocular Foreign Bodies in Military Practice. *Am. J. Ophth.* 1946 29 815.

The author discusses the management of intraocular foreign bodies in military practice. In 11 cases of suspected intraocular foreign bodies and multiple wounds of the face, a posteroanterior view of the skull was first obtained, and then a lateral view. The Waters position was used to exclude the confusing shadow of the petrous bone. More accurate localization was then accomplished by two methods: (1) a silver ring introduced into the cul-de-sac (22, 24 or 26 mm. in diameter), and (2) accurate Sweet's localization.

In some cases localization of a foreign body was obtained by the use of four small lead beads around the limbus in four different positions. Injection of air into Tenon's capsule before roentgenological examination clarified conditions in which the foreign body had perforated the eyeball and lay just outside the sclera. Fluoroscopy was disappointing.

Prejudiced adherence to either an anterior or posterior incision is unwise. When the foreign body is more than a few millimeters beyond the posterior capsule of the lens, a posterior rather than an anterior incision is wiser.

After the administration of sodium pentothal and anesthesia, supplemented by local anesthesia, the foreign body was approached usually through a new incision so placed as to permit the most direct approach to the object and as near the foreign body as possible because the magnetism of many modern instruments of war is so low that, to be effective, the magnet must be placed near the object.

The author's technique is as follows: After clearing the affected area of conjunctiva, Tenon's capsule, and episcleral tissue a black silk No. 4-0 suture is introduced into the sclera as a retractor. Another suture, No. 7-0, is inserted into the sclera just to one side of the foreign body for a depth of 0.1 mm. while a similar suture is introduced on the same level and depth just to the other side. An in-

cision is made between the last two sutures down to but not through the choroid, and the foreign body is removed by magnet or forceps. The sutures are tied the area about the incision is coagulated with the diathermy needle, and the episcleral tissue and Tenon's capsule are enclosed with silk sutures to avoid superimposing the incisions in the conjunctiva and sclera.

For foreign bodies in the anterior chamber or iris, essence is instilled preoperatively. If the foreign body has perforated the lens and is in the vitreous the corneal opening is made large enough to permit removal and the lens is extracted at a second operation.

The difference between the small and the large magnet is not the increased magnetic attraction of the larger magnet but the increased size of its magnetic field. A magnet should never be brought to the eye while alive. It is introduced into the wound, as near the foreign body as possible, and the applications are repeated.

Enucleation is now a last resort in the management of foreign bodies. Chemical endophthalmitis is not regarded as an indication for immediate enucleation if the foreign body can not be removed. The infection can usually be controlled by foreign protein therapy.

Postoperative care consisted of the application of 3 per cent atropine sulfate, sulfanilamide powder, 3 per cent boric acid ointment and a binocular bandage. At the end of 2 weeks a propioint shield was placed on the uninjured eye. Bed rest was required for 7 or 8 weeks. Penicillin was given in the evacuation or field hospital—25 000 Oxford units every 3 hours until 2 500 000 units had been given.

Canned milk and typhoid vaccine were used as foreign protein therapy.

Modern warfare has caused a greatly increased number of eye injuries but modern therapeutic methods yield a lower percentage of disability than that of previous wars. Exact localization by roentgenological methods is the secret of successful removal of foreign bodies. JOSHUA ZUCKERMAN, M.D.

Gordes, F. C., and Barber, A.: Changes in the Lens of Embryo after Rubella: Microscopic Examination of an 8 Weeks Old Embryo. *Arch. Ophth.* Chic. 1946 36 135

Microscopic examination was made of the eye of an embryo 7 to 8 weeks old from a therapeutic curettement performed 3 weeks after the diagnosis of rubella in a 35 year old primipara. The posterior portion of the eye was normal but showed retardation of development and differentiation of the lens.

The absence of the protection offered by the lids and Descemet's and Bowman's membranes in the cornea during the first 3 months of pregnancy may permit toxic agents to act directly upon the lens by way of the amniotic fluid. No cases of congenital cataract have been reported in which the mother had rubella after the third month of pregnancy and this may be explained by the presence of these barriers after that period.

It is of interest to note that there have been reported a total of 170 cases of rubella during pregnancy with congenital defects of the lens in 3 per cent.

WILLIAM A. MANN, M.D.

Bellows, J. G.: Influence of Local Antiseptics on Regeneration of Corneal Epithelium of Rabbits. *Arch. Ophth.* Chic. 1946 36 70.

The influence of antiseptics on regeneration of the corneal epithelium in rabbits is described. The author experimentally removed the corneal epithelium from rabbits eyes and simultaneously treated one eye with a given antiseptic drug and the other eye with normal saline and in every event the antiseptic drug appeared to retard the rate of regeneration. Some of the following drugs were tried: zinc sulfate (34 per cent), merbromin (2 per cent), phenol chloride, mercuric oxycyanide, metaphen methiodate, acriflavine, sephiran chloride, penicillin and sodium sulfathiazole.

The author concluded that in the presence of an infection penicillin and sulfathiazole should be used. HUNTER H. ROMANEY, M.D.

Larsson, H.: Results of Radiotherapy of Epibulbar Tumors at Radiumhemmet Stockholm, 1920-1940. *Acta radiol.* Stockh., 1946, 27 358

The results obtained in 66 cases of epibulbar tumors treated with radium at the Radium Institute Stockholm during a 20 year period are reported.

The usual method of treatment was the surface application of a weakly filtered radium preparation. Roentgen treatment in large doses was used in some of the advanced malignant tumors. With the use of surface applications of radium there seemed to be very little damage to the eye. Of the 46 cases treated by this method only one seemed to show a change which might be attributed to irradiation.

Benign nevoid tumors showed the best response to treatment. Of 14 patients with malignant melanoma 7 have been free of symptoms for 3 years or more. The majority of patients were treated by a combination of surgery and irradiation.

Numerous cases are reported in which there was no histological basis for malignancy as the author is opposed to biopsy of epibulbar tumors and believes there is danger of spreading the tumor.

WILLIAM A. MANN, M.D.

Ajo, A.: A Case of Chondroma Bulbi. *Brit. J. Ophth.*, 1946 30 465

The occurrence of cartilaginous tissue as a real tumor or even as part of a mixed tumor in a sound eye is very rare. Cartilaginous tissue generally occurs in eyes which have not developed normally or in healthy eyes which have been attacked by destructive disease. Cartilage may arise from connective tissue changes in an abscess in the vitreous or it may arise from the elastic choroid membrane. Hyaline cartilage also occurs in mixed tumors of the lacrimal gland. Two cases of chondroma of the eye lid have been reported in the literature.

fold to occupy the position of the posterior naris. Bilateral complete atresia may cause urgent symptoms at birth and may result in death from asphyxia. Some infants have a cyclical asphyxia which is relieved by keeping the mouth open others learn to breathe with the mouth open and have difficulty only while suckling and during sleep. They may suffer from starvation. In the presence of atresia, the affected side of the nose fills with mucoid discharge but complications due to infection were not common in the cases reviewed. Antral infection and orbital cellulitis were reported in some and adenoid facies developed.

Operative treatment almost always gives relief. Simple opening of the choanae may produce a cure but usually more radical measures, such as removal of part of the vomer are also necessary. The time of surgery varies according to the individual patient. The maintenance of nutrition and the risks of asphyxia may demand operation in early infancy. Various procedures have been attempted to prevent reclosure by granulation tissue. The radical method of choice combines perforation of the partition and removal of the posterior part of the nasal septum. Two cases are reported. A bilateral case in a child of three months who showed symptoms of asphyxia after birth later developed orbital cellulitis and proptosis. The child subsequently died from infection. Microscopic studies of the nasal structures are presented. The second case, a unilateral atresia in a male of 24 years, was treated successfully by perforation of the bony atresia by hammer and gouge and enlargement of the opening by bony forceps. The sinuses were clear to transillumination on both sides.

JOHN R. LINDHAY, M.D.

MOUTH

Fogh Andersen, P.: Harelip and Cleft Palate. *Acta chir. scand.*, 1946, 94, 3.

In Denmark the surgical treatment of harelip and cleft palate has been centralized to Diakonissestiftelsen's Hospital, Copenhagen, through the State Institute for Defects of Speech. The natal frequency has been found to be 1:50 per mille (195 to 123,306). Nine per cent of the afflicted were stillborn, 12 per cent died within 10 days of birth. The number of patients suffering from harelip and/or cleft palate is judged to be about 4,000 in Denmark and is distributed as follows: 25 per cent present harelip, 50 per cent, harelip associated with cleft palate and 25 per cent, isolated cleft palate.

The chief causal factor is that of inheritance. In this connection there are two genetically different deformities, i.e., harelip with or without associated cleft palate, occurring most often in men, with a manner of inheritance that is generally of a recessive character (conditioned dominance) and isolated cleft palate occurring most often in women, presenting a dominant manner of inheritance. Empirical figures for genetic prognosis show that eugenic measures are generally unnecessary.

A total of 1,000 patients were operated on by Fogh Andersen from 1934 to 1945. Infants are operated on under a light chloroform anesthetic, and adults under local anesthesia. The harelips are treated according to Veau's method when the child is 2 months old. In cases of associated cleft palate, the hard palate is closed at the same time. In bilateral cases each side is treated separately at intervals of from 6 to 8 weeks. Regarding cleft palate the technique varies according to the nature of the case.

Thirty-one of the 726 patients operated on for harelip and 3 of the 537 operated on for cleft palate died after operation. Thirteen of the deaths were presumably due to intercurrent diseases occurring 3 weeks or more postoperatively. 11 of the remaining deaths were due to postoperative hyperpyrexia.

The results of the harelip operations were in the main satisfactory both as regards the primary operations and the corrective plastics. As to the cleft palate operations the author cannot as yet evaluate the results. The anatomical result was generally good but he cannot judge of the functional result until the children operated on according to the modern technique have attained the age at which they are summoned for speech lessons at the State Institute for Defects of Speech.

NOAH D. FARRINGTON, M.D.

PHARYNX

Violé, P.: Schwannoma of the Pharynx. *Ann. Ot. Rhinol.* 1946 55, 334.

Schwannoma of the pharynx, sometimes called neurinoma or neurofibroma, has been reported only rarely. It apparently develops from peripheral nerve trunks in the neck, is benign and may appear at any age. It is encapsulated, smooth of surface, usually globular and is firm and fibrous unless degeneration has occurred. On section the tumor has a yellowish color and diagnosis depends upon the histological findings. The cut undersurface is glistening, and poor vascularity and the nuclei appear in a palisade-like arrangement. The location is usually anterior to the carotid artery or beneath the upper third of the sternocleidomastoid muscle. Growth is slow and extends over a period of many years. Throat irritation on swallowing may be the first symptom, later a Horner syndrome may appear. Normally these neoplasms are radioresistant and do not metastasize. The diagnosis requires a full microscopic study and aspiration biopsy is recommended. Differentiation from a carotid body tumor, also of rare occurrence, can be made only on microscopic examination.

JOHN R. LINDHAY, M.D.

NECK

Ficarra, D. J.: Struma Lymphomatosa: A Clinicopathological Study. *Arch. Surg.* 1946, 59, 779.

In 1912, Hashimoto described a pathological condition of the thyroid, characterized by a diffusely ex-

arged hard gland insidious onset chronic course, al pressure symptoms weakness fatigability and metimes nervousness The basal metabolism is not evated there may be symptoms of hypothyroid m. The disease is usually confined to women. icroscopically there is a dense, diffuse, lymphoid filtration between the follicles, with occasional rmation of secondary (lymphoid) nodules. There no formation of lymphoid sinuses nor of true lymphoid nodules Connective tissue is swollen and orily stained monocytes and plasmocytes may be und. Occasionally connective tissue predominates er lymphocytic infiltration The condition is called Hashimoto's disease, or struma lymphomatosa The ease is rare only 5 pathologically proved cases ere found among 720 thyroidectomies in 3 Brooklyn pitals In a fourth hospital among 1218 thy ideoctomies 27 cases of thyroiditis were reorted and of these the author concluded that not ore than 9 cases could have been struma lympho-atosa

In diagnosis the disease must be differentiated om Riedel's struma, chronic nonspecific thyroiditis ronic specific thyroiditis (tuberculosis syphilis tinomycosis) calcified adenomatous goiter lym osarcoma, and carcinoma. In Hashimoto's dis-ease, inflammatory symptoms are absent a specific rganism cannot be found and the gland is hard not ft. Calcified areas are not seen roentgenologically differs from a neoplasm in that there are no pal-ible nodules and the gland is not attached to sur-ounding tissue. The superior poles are extremely oad and the pyramidal lobe is enlarged It differs

from Riedel's struma in that struma lymphomatosa is practically always confined to women there is myxedema, glandular involvement is diffuse and bi-lateral, adhesions are absent the pyramidal lobe is prominent, fibrosis is circumscribed lymphoid hyperplasia is pronounced, and there are no Dorothy Reed cells.

Subtotal thyroidectomy is the method of treat-ment. Myxedema usually occurs postoperatively if not preoperatively the hypothyroidism should be treated by daily thyroid administration. Post-operative recurrence which is unusual, is probably dne to inadequate removal of diseased tis sue.

CLINTON H. THURNEZ, M D

Larsen, K.: Exophthalmic Goiter in Males. *Acta med scand.* 1946 125 71

This article is a review of the cases of exophthal-mic goiter in male patients admitted to the Medical Department of the Rigshospital Copenhagen during the war years

There was a significant increase in the number of males admitted with this diagnosis in the period from 1933 to 1936 male patients made up 12.6 per cent of the total number of exophthalmic goiter patients while in the period from 1941 to 1944 the corresponding percentage was 21

The author was particularly interested in the cases of masked exophthalmic goiter He found that the disease was masked in 26 of the 81 men (32.1%) and in 11 of the 93 women (11.8%) He thus concludes that exophthalmic goiter is masked more often in men than in women F J LIESEMAN, Jr M D

SURGERY OF THE NERVOUS SYSTEM

BRAIN AND ITS COVERINGS CRANIAL NERVES

Kozol, H. L.: *Pretraumatic Personality and Psychiatric Sequelae of Head Injury: Correlation of Multiple, Specific Factors in the Pretraumatic Personality and Psychiatric Reactions to Head Injury Based on an Analysis of 181 Cases*. *Arch. Nerv. Psychiat.*, Chic., 1946, 56: 245.

The author made a detailed study of the pretraumatic and the post-traumatic personality status in 181 civilians with acute head injuries. A clinical quantitative estimate was made of the degree of each of these specific personality factors. It was found that in a number of patients neurotic symptoms appeared for the first time after a head injury. In most patients psychological changes following head injury became most manifest shortly after discharge of the patient from the hospital, and were at a maximum in 3 to 6 weeks after discharge. The duration of post-traumatic symptoms varied but in general they were substantially receding at the end of a period of 3 months. However approximately 50 per cent of the patients showed some persistence of symptoms at 6 months. The duration of incapacity for work paralleled the persistence of psychological symptoms but most patients returned to work before they were entirely free of symptoms.

Patients with pretraumatic psychoneurotic personalities showed a greater proportion of post-traumatic psychiatric symptoms than did patients in other groups. However the patients with pretraumatic normal personalities were closer to the psychoneurotic patients than were members of other groups (psychovariant, psychopathic, etc.).

There was no close correlation between the severity of the acute injury of the brain, the duration of unconsciousness, and the severity of the sequelae but there was high correlation between the existence of persistent complicating psychological factors, such as continuing compensation pending litigation, occupational stresses and persistent associated bodily injuries, and the severity and persistence of psychiatric sequelae. The most frequent traits occurring after head injuries were periodic headaches, fatigability, tension diathesis, emotional instability, anxiety concerning the head, irritability, insomnia, timorousness, abulia, fitful sleep, difficulty in concentration and memory, seriousness, decreased gaiety, excitability, increased need of sleep and the occurrence of nightmares. GEORGE PIERCE, M.D.

Pitts, W. R.: *The Treatment of Penetrating Wounds of the Brain Produced by Missiles of Warfare*. *South. Surgeon*, 1946, 12: 88.

This article is based upon the author's experience as a neurosurgeon with 126 patients presenting penetrating wounds of the brain at a busy evacuation

hospital during the Italian campaign in the war just past. It is one of the clearest, most complete, and generally satisfactory reports to come out of the war in the literature dealing with specific types of skull injury.

Considerable stress is rightly placed upon the absolute necessity of careful preoperative study of the patient for his total injury as well as for his specific brain injury, of x-ray study of the skull, of treatment of the state of collapse (not shock) seen in these patients and the necessity of careful selection of the patients for surgery according to their obvious prognosis. The point is made that the signs of decerebrate rigidity are almost invariably an indication of the early death of the patient, regardless of what surgical care he may receive. Pits used local anesthesia (1 per cent novocain) in most of his patients, supplementing this only occasionally by intravenous administration of pentothal in the particularly unmanageable patient. A good account is given of what he found to be the most satisfactory manner in which to handle head wounds in general, and his special treatment for wounds of the dural venous sinuses, the paranasal sinuses, and the cerebral ventricles is described in some detail, yet with comfortable brevity. The use of chemotherapy (as it was then available) postoperative care, and the usual complications are discussed at some length. All of his observations are based on sound surgical principles which need not be applied to neurosurgery alone.

The author makes a strong plea that neurosurgery be just as carefully performed under the conditions of warfare as in civilian practice, stating that the ill effects of careless surgery and rough handling of the brain brings its toll in the wounded soldier just as it does in the sick civilian. One can read between the lines of this article and picture some of the difficulties he must have experienced at times in insisting upon and carrying out his principles of meticulous surgery which his colleagues knew were matters of genuine necessity with him. Such an article would have paid good dividends could it have been in the hands of (1) many young neurosurgeons and (2) hospital commanding officers during the past 4 years.

JOHN MARTIN, M.D.

Martin, J.: *The Surgical Problem of Intracranial Aneurysms and Related Vascular Lesions*. *Q. Bull. Northwestern Univ. M. School*, 1946, 30: 165.

In a series of 52 vascular anomalies of the brain, 17 were arterial aneurysms, 10 were arteriovenous fistulas, and 25 were congenital malformations. They were considered as a group because of the fact that they presented several common problems of surgical care.

The factor of trauma is one which must always be considered in the etiology of intracranial vascular

ions. In 2 patients with aneurysm severe head pain may have been a contributing factor and 2 other patients were suspected of having had trauma which could have been the cause of the lesion. The other 13 patients had no such history of trauma. In contrast 6 patients with fistulas had had craniofacial injuries which were believed without doubt to have been the cause of the lesion, 2 others had had trauma which could have been the cause and the other 2 had fistulas on the basis of congenital maldevelopment. The congenital malformations were so designated because no known trauma or other cause could be discovered for their existence. In none of the 52 patients was syphilis (present many years earlier in 1 patient with aneurysm) believed to be of any significance. The distribution of all three types of lesions according to sex was without significance and the age distribution was wide from 7 to 79 years.

In general the operative treatment of all three types of lesions was as direct and complete as seemed feasible in the light of the dangers to the patient from rough attempts at complete eradication yet it was conservative compared to the methods of treatment at some neurosurgical centers. Of the 9 patients with aneurysm who were operated upon all had carotid ligation in the neck, and 2 had clips placed on the intracranial aneurysm as well. Carotid ligation with good effect was done in 8 patients with a fistula and a ninth patient was subjected to ligation of an anomalous vessel in the posterior fossa. Craniotomy with partial dissection, desiccation and postoperative x ray or radium treatment were done in 11 patients with congenital vascular anomalies; 2 other patients were subjected to carotid ligation in the neck. A table summarizing the symptoms and treatment of all 52 patients is appended to the original title.

An attempt is made to clarify some of the confusing terms which have heretofore been used to describe the wide variety of congenital vascular anomalies of the brain. Instead of such terms as angioma, cavernous cavernoma, and circoid angioma, the lesions have been classified in their simplest anatomical terms.

JOHN MARTIN, M.D.

SYMPATHETIC NERVES

Lowbotham, G. F.: Migraine and the Sympathetic Pathways. *Brit. M. J.* 1946, 2: 319.

The author has postulated that the pain of migraine is probably due either to spasm or dilatation of the arteries of the scalp and dura mater and that the sensory arm of the painful pathways lies in the ophthalmic portion of the trigeminal nerve. He presents the theory that a migrainous person is born with an unstable mechanism in the hypothalamus which reacts excessively to the many stimuli that may reach it, either from the cerebrum or through the blood stream and thus causes explosive or dysrhythmic messages to be conveyed to the large blood vessels of the head. It is true that the large vessels

of the head are supplied with motor fibers from the efferent side of the autonomic nervous system, so that if disordered impulses from the hypothalamus are transmitted to the vessels concerned through the motor autonomic pathways, theoretically at least, relief should be obtained by section of those pathways.

Four cases of migraine all with operative treatment are presented. In 3 patients who obtained complete relief the operation consisted of removal of the lower half of the upper cervical ganglion stripping of the common external and internal carotid arteries so as to effect a periarterial sympathectomy (leaving the carotid body isolated but still in place) and then complete ligation and section of the external carotid artery. There was produced, of course a full blown Horner's syndrome on the side operated upon. In the fourth patient in whom the entire upper cervical ganglion was removed relief was only partial and the pain recurred. The author believes that in that particular patient the unstable mechanism may lie in the vessels themselves and not in the hypothalamus, or that an error was made in removing the whole and not just the lower half of the ganglion. The physiological basis for the last possibility is not explained. JOHN MARTIN, M.D.

Berry, R. L., Campbell, E. N., Lyons, R. H., Moe, G. K., and Sutler, M. R.: The Use of Tetraethylammonium in Peripheral Vascular Disease and Causalgic States. *Surgery* 1946 20: 525.

Recently a new method of producing blockade of the autonomic ganglia by means of parenteral injections of tetraethylammonium bromide has been introduced and the authors report deals with the use of the drug in peripheral vascular disease and causalgic states.

Observations were made upon the recumbent patient with the extremities exposed to controlled room temperatures. The color and the temperature of the skin and the volume of the pulses were noted in the basal state. Tetraethylammonium bromide was then given either intravenously (100 to 500 mgm.) or intramuscularly (on the basis of 20 mgm. per kgm.) one half of the total volume being injected into each buttock. The latter route was used only on patients under observation in the hospital. Intravenous injection of the drug caused a metallic taste within 20 seconds, a "cool sensation" in the extremities with definite increase in skin temperature and incomplete dilatation of the pupils with loss of accommodation. One minute after injection the systolic and diastolic pressures tended to fall particularly in the hypertensive individual, and there was an increase in the pulse rate. The vasoconstrictor gradient in the extremities was abolished so that toe and thigh temperatures assumed the same level.

In a series of 55 comparative tests of peripheral blood flow both on patients with peripheral vascular disease and on a control group it was stated that in 52 instances tetraethylammonium bromide proved equal or superior to the usually accepted methods of

producing sympathetic block such as paravertebral sympathetic block, spinal anesthesia, and sympathectomy.

In a study of 16 patients with functional angiospastic disorders (Raynaud's disease, 8; acrocyanosis and livedo reticularis, 4; Raynaud's disease with scleroderma, 4), there was a marked rise in skin temperature and an improvement of the clinical picture. In general it did away with the necessity of paravertebral blocks and was of aid in establishing the diagnosis by disclosing the presence of a functional vasoconstrictor component.

A group of patients with organic obstructive vascular disease (thromboangitis obliterans, 18; peripheral arteriosclerosis obliterans, 55) were observed. Eleven of the patients with Buerger's disease were treated with repeated sympathetic blocks by the drug of these, 5 are free from symptoms. The remainder of the patients treated conservatively have exhibited a satisfactory decrease in signs and symptoms but have had too brief a period of treatment for evaluation of the end results. However, in all of the cases the exercise tolerance was definitely increased. Fifty-five patients with peripheral arteriosclerosis obliterans received tetraethylammonium bromide, and from the results obtained it was concluded that one could prognosticate the value which might be derived from lumbar sympathectomy. Many of this group received relief from their nocturnal pain, a relief in some cases even greater than from morphine.

Causalgia, post-traumatic edema, or reflex sympathetic dystrophy was diagnosed in 17 patients. In these there was usually a transient and occasionally a sustained relief of pain on administration of the drug. In addition, it was stated that the drug aided in establishing a diagnosis of reflex dystrophy.

Apparently the drug relieved vasoconstriction by block of the sympathetic ganglia in 9 cases of thrombophlebitis—deep in 6 cases and superficial in 3. However, the effect was extremely variable in duration, ranging from a few hours to several days.

The authors have cited in detail at least one case of each of the types of peripheral vascular dysfunction treated with tetraethylammonium bromide in order to illustrate its effects. They state that they have used the drug 1,000 times in 500 patients without a significant toxic disturbance and add that most

toxic effects, reported elsewhere, have been of the transient type, probably being related to some peripheral circulatory collapse which can be readily corrected by an injection of epinephrine.

RICHARD C. SCHMIDT, M.D.

De Takata, G., Graupner, G. W., Fowler, L. J., and Jemik, R. J.: The Surgical Approach to Hypertension. Second Report. *Arch. Surg.* 61, 53-111.

The surgical treatment of hypertension is presented by the transdiaphragmatic method of Sack, including the preoperative and postoperative care, is discussed in considerable detail. The method of work up is described, as well as the criteria used by the authors as a basis for the selection of cases suitable for operative treatment.

Preoperative medication and anesthesia are discussed in some detail—points which the authors believe are of considerable importance in the operative procedure. The method of operation is also described in detail with illustrations, as well as the method of renal biopsy used by the authors.

A detailed follow-up system has been employed, and a summary of the results is tabulated. Cases have been divided into three groups: (1) those in which there was a clear cut indication for operation as indicated by preoperative studies; (2) those in which the operative indications were relative and debatable; and (3) those in which there was pre-nephritic and malignant hypertension, which cases were regarded as not suitable for operation.

In 17 patients in the first group the response was considered very good, and in only 2 was there recurrent hypertension, which was corrected after completion of a technically incomplete operation. Six patients showed recurrence in the second group. These recurrences were analyzed, and reasons were found for the organic irreversible lesions which could be detected preoperatively.

The authors concluded that at this time no single combined method of treatment can be identified as one which would give rigidly selected patients with hypertension as much benefit as the transdiaphragmatic splanchnic nerve section combined with dorsal lumbar sympathetic ganglionectomy.

HOWARD A. BROWN, M.D.

SURGERY OF THE THORAX

CHEST WALL AND BREAST

Mont E. S.: A Two-Stage Mastopexy in Plastic Surgery of Markedly Enlarged Breasts. *Ann. Surg.* 1946 124 112

The author states that of necessity excessively enlarged breasts often require surgical help. Frequently because of the marked increase in size a one-stage mastopexy is impractical to obtain the desired results, two-stage procedures frequently do obtain the desired results.

The purpose of surgery is four fold: (1) to obtain small breasts with reasonable size, shape, symmetry, and contour; (2) to construct two nearly identical breasts; (3) to obtain intact nipples and other areolae in the desired position; (4) to avoid loss of tissue following surgery.

When breasts are of exaggerated size the two-stage operation will meet all of these requirements and reduce variations to a minimum. Because such large breasts are usually functionless the prime purpose of the operation is to obtain small breasts of the desired proportions. A two-stage operation with reimplantation of the nipple may be utilized in such cases.

The author describes a two-stage technique with a great number of illustrations, and summarizes it as a method which allows for plastic reconstruction of excessively enlarged breasts with a minimum danger of losing any tissue. At the same time the procedure presents sufficient elasticity so that the surgeon may create small breasts of the desired proportions from an exaggerated deformity. Gentleness in handling tissues, meticulous surgery, careful planning of the surgery, and a knowledge of surgical anatomy are presupposed.

PAUL MERRELL, M.D.

Engelsen, C. D. and Stout, A. P.: Granular Cell Myoblastoma of the Mammary Gland. *Ann. Surg.* 1946 124 218.

Although granular cell myoblastoma is most commonly seen in the tongue, it may occur almost anywhere in the body and at any age. The authors have observed 5 cases in the mammary gland. Here it must be distinguished from carcinoma which closely resembles it.

These 5 cases are described in detail because the authors believe that they illustrate certain features which may be of aid in the diagnosis of myoblastoma of the breast. The authors believe this condition of the breast to be a benign tumor but agree that it is impossible to ignore the fact that it may on occasion become malignant and metastasize. They believe that this condition occurs in the breast and produces all the symptoms of early carcinoma, for which it may be mistaken and the breast needlessly sacrificed. The myoblastoma is easily recognized in a good frozen section.

EMIL C. ROBINSON, M.D.

Sjövall, H.: The Clinical Picture and Therapy of Rib Tuberculosis (Zur klinik und therapie der rippen tuberkulose). *Acta chir. scand.* 1946 94 33

The author has chosen for his discussion a series of 75 cases of tuberculosis of the ribs, observed at the surgical and orthopedic services of the University of Lund between the years of 1919 and 1938. The series was chosen because it permitted an adequate follow-up. Of the 75 patients, 45 were males and 30 were females—a ratio of 3 to 2. The average age of the patients in this series was 39 years which is far higher than the average age of a similar group of patients with extrapulmonary tuberculous lesions other than of the ribs. In this regard some significance may be attached to the fact that most of the patients were derived from a rural district where bovine tuberculosis was not uncommon.

The cases of rib tuberculosis fell into two main groups: in one group the rib involvement was but a part of a tuberculous process and in the second group the rib involvement was the primary and sole site of the disease. Thirty-one or 41 per cent of the patients had another clinical tuberculous lesion while in 16 there was a site of bone or joint tuberculosis.

Since the prognosis in rib tuberculosis is generally considered to be good it was a surprise to the author at the time of investigation to find that of his series of 75 patients 34 or 47 per cent had died. Moreover of the dead 62 per cent had died of tuberculosis.

Etiologically it was interesting to observe that 13 patients gave a definite history of trauma preceding the onset of the symptoms by a day or a week, and in half of these a palpable tumor was discovered within a week of the trauma. The authors feel that the occurrence of the injury merely called attention to the area of involvement in these patients. The symptoms were pain or the presence of a tumefaction. In 2 of the cases, the differential diagnosis between the lesion and breast cancer was considered. In 1 case there were acute symptoms which simulated a cholecystitis. In most instances, however, the process took the form of a typical cold abscess. The roentgen film was most productive, the diagnosis being established roentgenologically in 21 patients.

Sixty-one of the patients were treated surgically. Three methods were used: simple incision, incision plus curettage, and resection of the involved segment of rib. In all 3 groups, reoperation was necessary in some of the cases but the smallest number of reoperations were required in those patients who had been subjected to rib resection. In this instance, the rib was resected and the wound closed primarily. Of 44 patients so treated, healing occurred either by primary intention or soon thereafter in 31. Recurrence developed in but 3 of this group. However 20

of the patients were dead at the time of this review. Among these were the unhealed and recurrent cases. Furthermore the poor results in the last group were largely among those patients who had manifest tuberculosis in other parts.

The authors conclude that rib tuberculosis is best treated by rib resection but even with this treatment the prognosis both for healing and for eventual life should be guarded. WILLIAM C. BECK, M.D.

TRACHEA, LUNGS, AND PLEURA

Gartillet, E., Grasseet, and Houel, J: Hemothorax Walled Off by a Fibrinous Deposit; Impenetrable Hemothorax (*L'hémithorax cloisonné à dépôt fibrineux, hémithorax impenétrable*). *J. chir., Par.* 1946, 63 5

The problem of hemothorax has never received the attention that it deserved in the surgery of pleuro-pulmonary wounds. It has received surgical consideration only when it was thought to be septic. The problem of the evolution and sequelae of hemothorax is examined by the authors, especially as it develops into the so-called "clotted hemothorax" which cannot be evacuated by thoracentesis because it is surrounded by a tough impenetrable fibrinous wall.

The recent war has revived the problem of the clotted hemothorax. It has been estimated that between 10 and 30 per cent of hemothoraces evolve into this pathological entity.

In the clinical X ray study of traumatic hemothorax one sees an opacity at the base or lower third of the chest which may be resorbed in the space of 2 to 4 weeks if no infection occurs. This density may occur as high as the sixth interspace or higher and may be accompanied by pneumothorax and pulmonary embarrassment. Pulmonary collapse without effusion is suggestive. Symptoms are those of a pleural effusion—cough, pain, dyspnea—but generally they are not so severe. During the early stages these hemothoraces may be punctured and evacuated, but after 8 or 10 days, if no infection supervenes the situation may be very different. Although even then a complete evacuation of the bloody fluid may be accomplished, one may also encounter an impenetrable hemothorax. Clinically and roentgenologically the signs are identical with those of simple hemothorax, and the dry tap alone reveals its presence. Perhaps only a few cubic centimeters of fluid are evacuated from a cavity that appears massive in the roentgenogram. The opacity may be mistaken for a congested lung but this may be ruled out by lack of physical signs and by failure to evacuate fluid by thoracentesis.

Surgical exploration regularly reveals astonishing and characteristic lesions. On opening the thorax, one finds thick cords and strands of fibrous tissue forming a mass between the lung and pleura and enmeshed with blood. The lesion has the appearance of a vaginal hematocoele—it indeed is an immense hematocoele—and thus a dry puncture is explained.

When the hematocoele is removed with the finger or a knife, one finds a well delineated cavity. The adjacent lung does not lose its ability to re-expand, and the re-expansion can be accomplished by insufflation. After the twentieth day however exploration with a knife reveals the existence of a rigid fibrous wall 1 to 3 mm. thick which must be excised to free the lung. It is important to emphasize that the pleura and the lung parenchyma are normal under this capsule.

With regard to the pathogenesis of this lesion, it must be emphasized that the blood which coagulates into the pleural cavity does not clot, and stiffens only in fibrinogen. However the amount of fibrinogen in the hemothorax increases slowly and the clot takes on a fibrous character. Time is an important factor in its development, although not all hemothoraces are destined even in time to undergo fibrous change and become walled off. English authorities have postulated a humoral mechanism set off by the puncture wound which prevents coagulation. However, the authors believe that an instead attenuated infection is the important factor in its development. This low grade infection sets up a reaction in the fibrinogen-rich serous surfaces of the pleura which accounts for the fibrous character of the lesion.

Bacteriological studies in 17 cases revealed the presence of bacteria in these lesions—streptococci, staphylococci, and other gram-positive bacilli. There has been a definite increase in the incidence of walled-off hemothorax since the advent of sulfonamides and penicillin, the generalized use of which has attenuated many strains of bacteria. All of the patients had received either one or the other drug.

In some cases these hemothoraces eventually become absorbed, but in other cases serious sequelae (retraction of the thoracic cage, scoliosis, or reduction in vital capacity) occur after some months. This has been observed in several cases followed up since World War I. The authors conclude that a known case of walled-off hemothorax demands prompt surgical intervention.

The surgical procedures which may be employed are three: thoracentesis, thoracotomy and decortication. To wait longer than a day or two before thoracentesis is done allows the walling off process to occur. The fear that an early puncture will result in a new hemorrhage is unfounded, as the authors experience has shown. Sometimes a serous effusion exudate appears following an initial puncture, or a new density is seen in the roentgenogram, this calls for a new puncture and a search for organisms. The most optimum time for thoracentesis is the third day but this is not always practicable in the exigencies of war. Several successive punctures may be done and spaced from 24 to 48 hours apart, or a Mond trocar may be left in place and the chest tapped successively with only one initial puncture. Lavage of the pleural cavity with physiological serum aids in clearing up the lesion.

A walled-off hemothorax which cannot be evacuated by thoracentesis is a definite indication for

thoracotomy. Generally if it is done under 10 days it is sufficient to evacuate the fluid, remove all adhe- sive fibrous strands and clots with the hand within the pleural cavity and re-expand the lung by insufflation. A drain is left in place.

If the patient is seen from 15 to 20 days after the injury then one may predict that the pleural cavity is lined by the strong fibrous shell described and the lung incapable of expansion (proved by a trial in sufflation). The fibrous wall must then be removed by careful dissection, i.e. the lung must be decorticated until it re-expands under insufflation. Although penicillin has reduced the risks of postopera- tive infection decortication is still a formidable proce- dure and can generally be avoided if thoracotomy and early cleaning out of the thoracic cavity is done.

PILLIP B. CHASE, M.D.

Moore R. L.: War Injuries of the Chest. *Ann. Surg.*, 1946 124 367

Chest wounds comprise from one fourth to one- third of all battle casualties and about one twelfth of the wounds of soldiers that survive admission to medical units. The relatively low mortality rate for chest injuries in the present war as compared with all previous wars attests to the high quality of the therapy applied.

The proper treatment of thoracic wounds demands that the physiological alterations which accompany them be well understood. These may be due to (1) open pneumothorax, usually associated with sucking wounds of the chest wall (2) tension pneumothorax (3) surgical emphysema either superficial or mediastinal and (4) cardiac tampon- ade. All or any of these may be associated with a chest injury. Therefore it is most essential that they be kept in mind when a patient with a chest wound is first examined. All of them may be serious and if overlooked may lead to deaths which could have been prevented. The initial treatment of thoracic injuries consists mainly in combating shock, the proper care of the wound and correcting these phys- iological disturbances.

Open pneumothorax. The high mortality which followed early open drainage in the streptococcal empyemas of the last war was later proved to be due to the ill effects of the open pneumothorax that was produced by operation. When this method of treat- ment was changed and the pleural fluid in the early cases was evacuated by repeated aspirations rather than by open drainage the mortality fell from about 50 per cent to about 5 per cent.

When a hole is torn in the chest wall by a shell fragment or bullet, the effect is exactly the same as that of the establishment of open drainage in the early or acute stages of an empyema. Air is sucked in through the opening with each inspiration. The intrapleural pressure rises and the expansion of the lung is reduced. In order to compensate the patient breathes faster and with greater effort and this in turn rapidly leads to exhaustion. Open wounds of this kind so-called sucking wounds, should be

closed as soon as possible. Experience has shown however that closure by suture is inadvisable unless all of the necessary surgery has been completed. When the existing facilities are inadequate for this, or trained personnel is not available, treatment in general should be limited to first-aid measures namely control of shock control of hemorrhage, ex- cision of devitalized and soiled tissue, and removal of readily accessible foreign bodies. The wound is then covered with a pad of vaselined gauze. This is either sutured to the skin, or strapped in position with ad- hesive plaster. In most instances this method will suffice until the soldier can be delivered to a suitable hospital for definitive operating.

Tension pneumothorax. When a lung is pierced or torn or more rarely when a bronchus is lacerated air may repeatedly be sucked into the pleural cavity during inspiration, and trapped. The opening act- ing as a ball valve allows the air to get in, but does not allow it to get out. Under these conditions, the intrapleural pressure steadily increases and the re- sulting tamponade effect may reach alarming pro- portions and seriously interfere with both pulmonary expansion and the filling of the right side of the heart. This leads to severe dyspnea and in extreme instances to acute circulatory failure evidenced by a falling systemic pressure, a high venous pressure and a weak rapid pulse, pallor and sweating. In civil practice this condition known as a tension pneumo- thorax, is occasionally seen after pneumonectomy or lobectomy when the closure of a bronchial stump or lung is insecure or gives way in the presence of infection. It may also follow rupture of an em- physematous bulla. It is more likely to be due to laceration of the lung or bronchi by fragments of broken ribs. The immediate treatment is very simple. The pressure can be relieved quickly by in- troducing a needle with a flange, which can be readily strapped to the chest wall. If such a needle is not available, a flange can be improvised by using an ordinary cork. The needle is inserted through the cork which in turn is fixed to the chest wall with adhesive strapping. The second intercostal space in the midclavicular line is a convenient location for introducing the needle. If left in position the needle should be connected with a water-seal.

Surgical emphysema. Surgical emphysema is superficial or mediastinal. The superficial variety may result from laceration of the lung by in-driven rib fragments or penetration of the lung by a missile. In either case air escapes into the subcutaneous tis- sues, either directly from the lung at the site of an adhesion or indirectly through the medium of an interposed pneumothorax. From the chest wall the air may spread upward to involve the tissues of the neck and face, or downward to the abdominal wall or even to the extremities. The diagnosis is readily established by the crackling sensation which one gets on palpating the involved areas and the air in the tissues is easily recognized on roentgenograms. The condition rarely demands any special treatment be- cause the opening in the pleura usually becomes

sealed after a short period of time and the air in the tissues is readily absorbed. If the pleural opening does not close however and the condition becomes progressive and causes symptoms, relief should be obtained by introducing a needle into the pleural space for the escape of the air.

Mediastinal emphysema is a much more serious condition because air escaping into the mediastinum does not find a ready outlet and there is serious danger of compression of the great vessels and even the esophagus. Here the air escapes from a lacerated trachea or large bronchus and tends to spread toward the neck.

This condition is readily recognized from a soft swelling in the suprasternal notch and the diagnosis can be confirmed roentgenographically. Radical treatment is indicated only when the symptoms of compression are severe enough to endanger life. Treatment is directed toward relief of pressure. A thoracotomy may be necessary followed by incision of the mediastinal pleura and suture of the lacerated bronchus or trachea.

Cardiac tamponade. Cardiac tamponade refers to acute cardiac compression caused by the rapid accumulation of blood or exudate within the pericardial sac. Since the pericardium is a dense, fibrous, relatively inelastic membrane it is not distended appreciably by an acute increase in pressure. The pressure of the fluid obstructs the filling of the heart and the blood is dammed up in the great venous reservoirs of the body. Should the intrapericardial pressure equal the effective venous pressure, the blood can no longer enter the right auricle and death follows. The clinical picture is that of circulatory failure.

In chest injuries, the syndrome is caused by intrapericardial bleeding which usually results from a stab wound in the front of the chest to the left of the sternum, in the third or fourth interspace. The source of the bleeding is most likely to be the right ventricle or the anterior descending branch of the left coronary artery.

Treatment demands the greatest haste, to relieve the pressure and to stop the bleeding. The time required for roentgenologic and fluoroscopic examinations, and long preparation might mean the difference between life and death.

Hemothorax. Hemothorax occurs in 70 per cent of all chest injuries in modern warfare. Notwithstanding, the treatment has been a subject of much discussion. Some have advocated extreme conservatism, aspirating only to relieve pressure or pain. Others have advocated aspiration with air replacement, and still others, aspiration alone. This latter method, with a view toward emptying the pleura as quickly and completely as possible, is now widely approved as the treatment of choice.

When a hemothorax cannot be controlled by aspiration because of clotting, the proper treatment is an early thoracotomy with evacuation of the blood clot. The treatment of chronic hemothorax by excising the fibrous membrane covering the under

lying lung appears to have reduced the incidence of chronic empyema in the present war.

Wounds of the chest wall. The treatment of wounds of the chest wall does not differ from the treatment of similar wounds in other parts of the body except that chest cases should have a high priority among battle casualties, and should be taken as quickly as possible to an installation with complete anesthesia and operative facilities, preferably one with personnel experienced in thoracic surgery. Endotracheal anesthesia should be resorted to in all intrathoracic procedures, and facilities for suction should be available. The wounds should not be sutured until all of the surgery, necessary at the time has been completed. Suturing then should be directed primarily toward closing the pleura. When it is necessary to approximate muscle and fascial layers of the chest wall these structures should be sutured loosely. The skin and subcutaneous tissue should be left open.

Penetrating wounds. The treatment of through and through bullet wounds of the chest which cause slight pulmonary damage and do not injure any blood vessels or other important structures consist mainly of the treatment of hemothorax.

Penetrating wounds with retained foreign bodies. In treating these injuries the risk of the operative procedure which would be required for removal of the foreign body has to be balanced against the risk of complications which are likely to develop if the foreign body is left in place. Experience has shown that pieces of clothing and fragments of bone are especially likely to lead to serious infection and every effort should be made to remove these. On the contrary metallic foreign bodies are well tolerated. Nevertheless, it is thought that these should be removed also when they are large (diameter of 1 cm. or more) and causing symptoms, when free in the pleural space with hemothorax, or because of their position, considered to be a threat to vital structures such as the heart, esophagus, and large blood vessels.

Thoracoabdominal wounds. Whenever a missile penetrates the thoracic cavity the possibility of its having traversed the diaphragm and entered the abdomen must always be borne in mind. This is particularly important if the thoracic wound is low, in the region of the diaphragm. Roentgenograms of the abdomen as well as of the chest should be taken regularly. When operation is being planned, careful consideration should be given to all the facts relative to both the thoracic and abdominal wounds. There is no standard procedure that can be applied in all cases.

Infected war wounds of the chest. The treatment is as follows: (1) pleural and pulmonary sequestration are forestalled by early operation (within 6 to 10 hours) removal of foreign bodies, local and systemic use of the sulfonamides or penicillin, and leaving the superficial layers of the wound in the chest wall open. (2) Infected hemothorax in the early stages is properly treated by aspiration. Thoracotomy with no resection (open drainage) should be postponed until

the pleural exudate is definitely purulent and (3) pulmonary or pleuropulmonary suppuration secondary to retained foreign body should be treated first by drainage.

STEPHEN A. ZITMAN M D

Wylie, R. H. Hoffman, H. L. Williams, D. B. and Rose W F: *The Thoracoabdominal Casualty*
Ann. Surg. 1946 124 463

This report reviews the case records of 903 thoracoabdominal casualties in the Forward Hospital of the second Auxiliary Surgical Group during 1943-1944 and 1945.

The term thoracoabdominal wound refers to a wound produced by a missile perforating the diaphragm and entering the pleural and peritoneal cavities. Casualties in which the pleural cavity and peritoneum have been entered by separate missiles without injury to the diaphragm are excluded. Thoracoabdominal wounds comprised 25.5 per cent of the abdominal cases treated surgically at this hospital.

The pattern of entry of the fragments or bullets in thoracoabdominal wounds shows that 837 of the missiles entered through the abdomen. The entrance wounds in the chest were equally distributed on the right and left sides.

The intelligent regimen of resuscitation and treatment depends on the early recognition of the thoracoabdominal feature of the wound. For practical purposes any perforating fragment which crosses the horizontal zone bounded by the plane of the costal margin and twelfth rib below and the line between the nipple and the angle of the scapula above may perforate the diaphragm. When a penetrating wound was present, roentgenological examination was a necessity. Further clinical examination of the casualty was directed at an evaluation of the cardiorespiratory status. However in thoracoabdominal wounds less time could be devoted to stabilization of the cardiorespiratory physiology than in the purely thoracic cases. Of prime importance in combating shock and saving life in thoracoabdominal wounds is early operative treatment. Examination and all necessary preoperative therapy were done in the so-called shock tent.

With the movement of the casualty from the shock tent to the operating tent by stretcher the operative phase of management begins. It deals with the anesthesia, pathology operative approach and procedure. In nearly all cases maintenance anesthesia was achieved by endotracheal ether and oxygen in a closed circuit. Injury to the lung was described as contused containing hematoma or as perforated or lacerated. Because of the path of the missile through the lower part of the chest in the diaphragmatic zone, the peripheral portions of the lower lobes and less frequently of the middle lobe and lingula of the left upper lobe were injured.

The injury to the diaphragm was a single or double small perforating wound, the large lacerated wound, or the avulsion of the diaphragm from its chest wall attachment. Similar to the chest wall, the right and

left sides of the diaphragms were wounded quite equally.

In the peritoneal cavity the liver took the impact of the missiles entering through the right diaphragm. In order of frequency the right kidney, the colon, the stomach, the small bowel, the duodenum, and the gall bladder were wounded on the right side.

The anatomic relationships below the diaphragm have a direct bearing upon the operative approach and procedure on the right or left side. Any discussion of methods of approach must be qualified at the outset by the statement that no one approach is ideal for all patients and the judgment of the surgeon who knows the individual patient and his own capabilities decides the approach to be used by himself. In general when a thoracotomy and celiotomy were both contemplated the chest procedure was performed first, because the patient stood a celiotomy better after the chest wall and diaphragm had been closed and the lung re-expanded. How much surgery should or can be done through the chest and diaphragm, and how much through the abdomen again depends upon relative factors.

Thoracotomies as performed, were of four types: (1) a limited thoracotomy achieved by extending the missile wound; (2) a thoracotomy through the area of the wound; (3) a thoracotomy outside the area of the wound; and (4) a so-called combined thoracoabdominal incision, in which the thoracotomy was extended through the costal arch and down through the abdominal musculature.

The closure of the diaphragm is of utmost importance both on the right and left sides. Suture of the left diaphragm is imperative to cut off the path of contamination and infection from the peritoneal cavity and to prevent herniation of the abdominal viscera into the pleural cavity. It is likewise mandatory to close the right diaphragm to prevent the occurrence of bile pleuritis and empyema, and also to keep contamination and infection from invading the pleural cavity. A firm closure was insured by interrupted silk sutures.

Specific treatment of individual organs of the abdominal cavity revealed that wounds of the stomach and duodenum were sutured, wounds of the colon were exteriorized, wounds of the small bowel were treated by suture or by resection and anastomosis of the spleen by splenectomy and of the liver by subcostal drainage. Wounds of the kidney were treated by nephrectomy only when hemorrhage was persistent, or the pelvis involved otherwise drainage sufficed. Treatment of the pancreas was by suture and drainage, or by drainage alone. The celiotomy incision was either a right or left rectus, and closure invariably entailed some type of retention suture.

The postoperative care of the patient with a thoracoabdominal wound entails attention to details of care common to both the chest and the abdominal patient.

The postoperative care of the chest is directed toward maintaining cardiorespiratory balance, promoting expansion of the lung and removal of blood

and air from the pleural cavity to allow full expansion and to minimize the chances of pleural thrombus formation.

The postoperative care directed at the abdominal part of the wound emphasized the importance of nasal tube stomach siphonage, up to 4 days, in accord with the re-establishment of peristalsis to the surgeon's satisfaction. Use of stomach siphonage indiscriminately beyond the period of 4 days may veil a bowel obstruction, and delay recognition and correction of it.

An accurate knowledge of the daily intake and output of the patients is imperative. During the period in which nasogastric siphonage was in use between 1,000 and 3,000 c.c. of 5 per cent glucose in saline solution were given to these patients daily. Caution should be exercised in giving a total amount of parenteral fluids in excess of 3,000 c.c. daily because of the impaired cardiorespiratory reserve which may exist and the possibility of producing pulmonary edema.

Sulfonamide and penicillin therapy were employed from the time of wounding through the postoperative period. Complications recorded in order of frequency were staphylococci, empyema, subphrenic abscess, and pneumonia. Bronchopleural fistula was reported 4 times, twice with empyema, and twice with bile empyema. Pressure pneumothorax occurred in 3 instances as a postoperative complication.

The gross mortality for the 993 cases with thoracoabdominal wounds was 246 or 24.7 per cent.

STEPHEN A. ZUCKMAN, M.D.

Shefts, L. M., and Doud, E. A.: The Management of Thoracic and Thoracoabdominal Wounds in the Forward Area in the Sicilian and Italian Campaigns. *J Thorac Surg* 1946, 15, 205.

The method of treatment and the immediate results of 64 thoracic and thoracoabdominal war injuries with wounds limited to the chest wall, are reported. The cases were selected from a group of 500 patients who had been treated by a team of the Second Auxiliary Surgical Group during a 20 month period commencing with the invasion of Sicily. The patients were evacuated from this first priority field hospital to the chest center of a base hospital in from 8 to 15 days following emergency surgery; therefore the results are uncorrected for the development of subsequent complications and for lethality of concomitant wounds.

Bullets tended to involve more than one celomic cavity and, because of wobbling or high compression wave, to cause contusion of organs and extensive pulmonary hematomas. High explosive fragments have greater tearing action.

Preoperative intercostal nerve block covering two segments above and two segments below the wound in the chest wall, permits a painless cough to clear the tracheobronchial tree. If cough is inadequate endotracheal catheter suction is used at once. Intravenous fluids are given only after an open air

way is established. Hemopneumothorax, occurred in 159 of 500 cases was treated by karyolipin thoracostasis with autotransfusion of striated citrated blood, when feasible. True, progressive tension pneumothorax was rare in this series, perhaps because air leaks were sealed by hemostasis at the site of the tear. Sucking wounds were closed with large occlusive petrolatum pads. After resuscitation, fluoroscopy for position of the mediastinum for cardiac tamponade was done. Roentgenograms can usually be made in the upright position.

Intra-abdominal injury can be postulated from position of the wound of entrance, position of the missile, and failure to respond to shock therapy. Deep shock occurs in intraperitoneal hemorrhage, a gross contamination of the left pleural cavity by contents of the large bowel, in shattered spleen, and wounds of the right lobe of the liver. Immediate exploration is indicated after insertion of a Levine tube in the stomach.

Surgical treatment of penetrating and perforating wounds is based largely on the presence or absence of continued intrathoracic hemorrhage, and steps from local debridement and closure to extensive surgical procedures. Rarely is thoracotomy done because of the presence of missiles. They are removed if convenient, or if they lie in a position which is dangerous to life—the hilus of a lung, the mediastinum, or near the esophagus. Torn pulmonary parenchyma is rarely sutured.

Traumatic thoracotomy arbitrarily means evacuated wounds, palm sized or larger involving the pleural cavity. Treatment is designed to eliminate paradoxical motion and permit closure, without tension, with nonabsorbable material for fixation against cough until the wound is solid, gross contamination notwithstanding.

Thoracoabdominal wounds in which a single missile involves the pleural cavity, diaphragm, and peritoneal cavity are discussed as left and right sided penetrating and perforating wounds, and the optimum surgical approach for each is outlined.

The technique of approach to mediastinal structures, the control of hemorrhage, and the details of mediastinotomy are presented. The prevention of treatment of infection of the subscapular space in chest wall wounds is considered. The prognosis in combined thoracic and spinal cord injuries, with the level of anesthesia higher than the umbilicus, was found to be hopeless because of paralysis of the ribs and ineffective cough.

The postoperative goal is a completely expanded lung. It may be achieved by the anesthetist in conjunction with pleural lavage at the time of closure, and maintained in the presence of a clear tracheobronchial tree. Energetic cough routine is supplemented by intercostal nerve block when pain is an inhibitory factor. Tracheal toilet with catheter rotation and bronchoscopy are freely used postoperatively. Oxygen may be used for short periods.

With an open airway established, endotracheal anesthesia with pentothal or nitrous can be induction

is used with ether for maintenance. Endotracheal catheter suction during surgery to prevent spill-over of secretions and postoperative bronchoscopy are essential.

LYNN JOHNSON M.D.

D'Antona, G. G., and Fojanini, G.: Pleural Complications in the Course of Suppuration of the Lungs (Sulle complicanze pleuriche in corso di suppurazione polmonari). *Policlinico sez. chir.* 1946 53 45 91

In abscesses of the lung the pleura may become involved by direct extension, or through the lymphatics if the abscess is near the surface. In the lung the lymphatics near the surface run toward the pleura while the deeper ones run inward, but in deeper abscesses the lymphatic current may become reversed by its being blocked and carry infectious material to the pleura. And of course, in operation on the lungs infection may be disseminated.

From November 1938 to October, 1943 198 cases of suppuration of the lung were admitted to the University Hospital of Rome. Among these 61 (30.8%) presented pleural complications of various types and in 7 of these the complication was bilateral which made the total number of complications 68. The mortality of pleural complications in these cases was 8.53 per cent, the total mortality being 26.6 per cent. There was a total of 52 deaths 17 of them, or 32.69 per cent, from pleural complications. Of the deaths from pleural complications 6 or 35.3 per cent, were due to simple empyema and 11 or 64.7 per cent, to putrid empyema. In 4 other cases the pleural complication was not the direct cause of death death being due to hemorrhage in 3 cases and to diffusion of the lung process in 1 case.

The localization of the pleural complications is discussed in detail and illustrated. Histories of a number of the cases are given.

In only 1 of the cases was the empyema bilateral. It has been claimed but not demonstrated that there are direct lymphatic communications between the two sides of the pleura. It is true that the empyema may mask an unrecognized lung abscess and although such abscesses can be located by roentgen examination, this is not always true and it may be necessary to make the diagnosis from the history. Serofibrinous pleuritis are generally benign and have a marked tendency toward spontaneous absorption. A rise of temperature after operation which is prolonged and tends to reach a considerable height indicates the possibility of a developing pleural complication. Puncture of the pleura should be performed very carefully in such cases. If the fever persists for too long it indicates the transformation of a serofibrinous pleuritis into a purulent or putrid one. In serohemorrhagic pleuritis, puncture gives a red fluid.

In seropurulent pleuritis the pleural reaction is more intense and the clinical picture more marked. The fever is higher and remittent and the patient's general health is affected. The exudate may increase to such an extent as to cause dyspnea and symptoms from displacement of the mediastinum. The course

is longer than in the preceding forms. In purulent pleuritis the patient has violent pain in the affected side of the thorax and dyspnea. The general condition grows worse rapidly. The physical signs are very marked in these cases. In putrid pleuritis the symptoms are much the same but more violent there may be severe toxemia and the process progresses.

Roentgen examination is used to differentiate between accumulated pyopneumothorax and suppurative lung cavities. Illustrative roentgenograms are given. Lung cavities are generally situated in the peripheral part of the organ, most frequently in the lower right lobe. When infectious material is aspirated it passes more readily into the right bronchus than the left because the former follows more nearly the direction of the trachea. Large areas of air and fluid are more apt to be of pleural than of pulmonary origin. If fragments of tissue project into the clear area they are apt to be of lung tissue and the condition is a lung cavity. The surface is smoother in hydrops of the thorax than in lung cavity. In empyema beyond the limiting band the lung tissue is normal while in lung cavities the passage from diseased to normal tissue is gradual. The angle of the circular shadow with the wall of the thorax is acute in pneumothorax and obtuse in cavity. There is no absolutely certain differential roentgen sign between these two conditions but a number of signs which taken altogether generally suffice for differentiation. In making the roentgen examination the patient should be placed in the position he will assume on the operating table. Anteroposterior and laterolateral views are taken.

In order to decrease the very serious mortality in this condition there should be close collaboration between the physician, surgeon, and roentgenologist. The patients should be sent to the surgeon at once without waiting for pneumothoracocentesis or treatment with sulfa drugs or arsenobenzol after roentgen examination operation should be performed at once, preferably by the technique of free thoracotomy.

AUBREY G. MORROW M.D.

Dahl Iversen, E., and Møller P. E. The Differential Diagnosis and Treatment of Tuberculomas in the Lung. *Acta chir scand.* 1946 94 243.

The problem is posed as the differential diagnosis of an isolated tuberculous process in the lung and a tumor, an infected cyst, and a chronic lung abscess. It is shown that the differentiation of these conditions even under the most ideal conditions, is extremely difficult or impossible without exploratory thoracotomy. Three cases are presented in great detail to show the difficulties encountered. A fourth case was diagnosed as unilateral cavernous tuberculosis with roentgenographic changes suggestive of carcinoma. The suggestive findings in this case proved erroneous on exploration.

The pathological picture in these cases was that which is clinically termed tuberculoma and which pathologically is called a conglomerate tubercle. The lesion occurs oftenest in the basal part of the cerebrum in the cerebellum and the pons and in the

spleen. The authors state that they have been unable to find a description of this lesion in the lung in the newer texts of pathological anatomy.

It is stated that tuberculomas of the lung should be removed and that the operation of choice if the pleural cavity is free, is lobectomy because resection of the lung carries the risk of tuberculous infection of the pleura from the resected surface. This statement is not based on experience with regard to the course of nonoperated pulmonary tuberculomas but on the fact that the course of tuberculoma in other sites is one of progression. One of the cases cited tends to show this.

The roentgenologist presents his view of the subject and without the history, physical findings and laboratory data his task is next to impossible. Lung tumors may be polymorphous and they can be confused with many other pulmonary conditions. The differential diagnosis from tuberculosis in its various forms often has to be considered and in many cases cannot be positively resolved by this method of investigation. In view of the authors' experience thoracotomy has been necessary for definitive diagnosis.

EDWIN W. PARSONS, M.D.

HEART AND PERICARDIUM

Günther, A.: Ligation of the Ductus Arteriosus. *Edinb J. M.*, 1946 53: 346.

Forty patients ranging from 4 to 51 years of age came under observation for a patent ductus arteriosus. The diagnosis was confirmed by operation in 19 of them. Four patients were found to have an infection superimposed upon the anatomical defect. Of these 2 patients succumbed shortly after admission and 3 patients were operated upon. A brilliant result was obtained in 1 case but a fatal outcome attended the other two interventions.

Thirty-six patients had no evidence of superimposed infection. Of these 16 were operated upon a second operation being done on 1 patient because of recanalization of the ligated ductus within 3 months. One patient was not benefited 3 patients died and the condition of 13 was materially improved.

The clinical and radiological features of the condition are described. The continuous, or "Gibson" murmur is almost certainly present by the age of 5 years even though it may be absent before that age. The accentuated pulsations of the pulmonary artery the forceful contraction of the left ventricle at fluoroscopy and the behavior of the blood pressure after exercise are elaborated upon.

Cases having evidence of an infection of the pulmonary artery or ductus are believed to constitute definite indications for surgical intervention. Evidence of such infection lies in the presence of septicaemia usually with cultures positive for streptococcus viridans and signs of pulmonary involvement such as multiple infarcts superimposed upon the signs of a patent ductus.

In the noninfected cases ligation should probably be recommended if there is no evidence that the

ductus is closing spontaneously in patients up to 15 years of age. After the age of 10, ligation is recommended if impairment of function is noted, or after the age of 20 it is justifiable for threatened heart failure or grave symptoms.

Brief allusion to detail of the surgical procedure made and illustrated case reports are appended.

IRVING T. LAMSON, M.D.

Mercer, W.: Patent Ductus Arteriosus and Its Surgical Treatment. *Edinburgh M. J.*, 1946 53: 341.

The author describes in brief detail the surgical procedure employed. An anterior incision is not usually entering the pleura in the second interspace. The phrenic, vagus and recurrent laryngeal nerves are visualized and spared. The management of the ductus itself follows the techniques of Gross and Tonnoff. Dissection is kept preferably against the aorta. Overlapping of the ductus by the adjacent pulmonary artery or by an extension of the pericardium is occasionally noted.

The explanations for recanalization are reviewed and the technical steps designed to prevent this are pointed out. The author apparently uses unbraided silk sutures or ligatures, but does not point out division of the ductus.

Attention is called to the changes in blood pressure which occur as a result of ligation, and the sometimes dramatic clearing of the blood stream of organisms in the infected cases is pointed out.

IRVING T. LAMSON, M.D.

ESOPHAGUS AND MEDIASTINUM

Wellin, S.: A Contribution to the Roentgen Diagnosis of Limited Esophagitis. *Acta radiol. Stockh.*, 1946 27: 451.

The occurrence of nonspecific inflammatory changes in the esophagus has long been recognized, but neither the pathological anatomy nor the roentgen details of the entity has received any extensive systematic investigation until recent times.

The postmortem examinations have revealed the changes discovered occurred *intra vitam*. The possibility that gastric juices enter the esophagus after death and cause changes consistent with esophagomalacia acida had to be ruled out. Microscopic studies however clearly proved that the changes were inflammatory and that a definite esophagitis existed. Some maintain that even various stages—acute, subacute, and chronic—can be distinguished. The changes are confined for the most part to the lower esophagus. They may be confused with an ulcerative esophagitis but others think that they do not seem to fit into any of the usual classifications. The process is essentially an inflammatory one causing deep changes in the walls which eventually lead to a spasmlike stenosis. The symptoms are easily and frequently misleads to a diagnosis of cancer of the esophagus.

Wellin reports 9 cases in patients ranging from 16 to 83 years of age. The dominant symptoms were 1

Fig. 1

Fig. 2

Fig. 3

Fig. 4

Fig. 1 (Welln.) The initial stage of the disease, showing the coarse outline of the mucous membrane.

Fig. 2. The florid stage showing the typical changes, elongated funnel shaped constriction of the distal part, fairly distinct superior boundary, notched contour and dilatation above.

Fig. 3 Two years and 3 months later. The patient has now reached the final stage. The stricture at this stage of the disease is more pronounced, and the "funnel" greatly shortened.

Fig. 4. Pronounced constriction and distinct limitation of florid stage.

progressive dysphagia, frequently at first merely a feeling of some obstruction behind the lower part of the sternum to the passage of solid food but gradually this became worse until only finely divided or liquid food could pass through the esophagus; pain, described as a feeling of cramp behind the sternum, and hematemesis occurred later.

Three stages of the disease are recognized. The initial stage shows inflammatory changes limited to an edematous slightly bulging and easily bleeding mucous membrane. The florid exudative stage shows a normal or slightly reddened mucous membrane, and a narrowed lumen strongly inflamed and covered with fibrin. The upper limit of the constriction has a distinct, very sharp and often lineal horizontal demarcation.

The clinical picture of esophagitis is such that clinicians will initially suspect a malignant process until the roentgenological changes are characteristic in the more advanced cases of this disease. An elongated funnel shaped constriction with notched contours in the distal part of the esophagus a relatively distinct superior boundary and a cephalad

dilatation of the process permit a diagnosis differentiating esophagitis from cancer.

Notwithstanding the benign histological nature of the process the prognosis is very serious and in a large number of cases gastrostomy will sooner or later be necessary.

STEPHEN A. ZIEGLER, M.D.

Jacobson F: A Patient with Cancer of the Esophagus, Alive and Free from Evidence of Tumor 6 Years after Roentgen Treatment. *Acta radiol* Stockh., 1946 27 351

Treatment of cancer of the esophagus still yields poor results and 5 year cures after roentgen treatment are rarely reported in the literature. The author reviews some 9 cases reported but notes that histological proof of the diagnosis was lacking in about half of the cases. He urges that every case of carcinoma of the esophagus surviving more than 5 years be described with details of treatment and sequelae in order to continue the improvement of the treatment.

The author reports the case of a patient treated for cancer of the esophagus who was alive and free

from tumor more than 6 years after the treatment. He was 58 years old when first seen in 1939. A diagnosis of carcinoma of the lower third of the esophagus was made with x-rays. Biopsy showed a squamous cell carcinoma with low differentiation. The chest roentgenogram and electrocardiogram were normal and no evidence of metastases was found.

The patient was treated by the method of Strandqvist with crossfire radiation from three anterior and three posterior fields. The patient received 3,600 r per field, except in the posterior central and the anterior lateral fields, each of which received 3,400 r. The treatment was given with about 175 kv and an intensity of about 50 r per minute, measured on the surface of the skin. As a filter $\frac{1}{4}$ mm. of copper plus 1 mm. of aluminum was used. The size of the fields was about 6 by 13 cm. The tumor dosage was estimated at about 5,000 r over 35 days.

The patient developed a blistering epidermatitis from the treatment but was clinically improved. Two months later the barium study of the esophagus was normal. Three months after the treatment the patient developed an induration in the right lung which cleared after 9 months. This was considered a radiation reaction.

The patient's heart began to enlarge 3 months after treatment but after a year the size remained stationary. After 5 years, the electrocardiogram showed signs of intraventricular conduction disturbances, a lesion presumably due to the treatment.

Three years after the treatment the patient developed a right pleural exudate which necessitated aspiration several times for the next 3 years. The exudate never showed tumor cells; therefore it seems likely that pleural metastases did not exist, and the exudate was probably due to the treatment.

More than 6 years after the treatment the patient was cured locally, had no difficulty in swallowing, and had no noticeable metastases. He had a slight hacking cough, became breathless, and had pain in the middle of his chest with exertion. These symptoms somewhat limit his capacity for work.

ROBERT R. BENTLEY, M.D.

MISCELLANEOUS

Scott, O. B., and Morton, D. R. Primary Cyst Tumor of the Diaphragm. *Arch. Path. Clin.* 1946 41: 645

The paucity of reports on primary diaphragmatic neoplasm indicates the rarity of this condition. In a recent review of this subject, the authors found reports of 33 benign and cancerous diaphragmatic tumors. Their series includes 4 cases; the diagnosis in these was not confirmed by operation or autopsy. It is anticipated that with the increased use of roentgen fluoroscopy and roentgenography of the chest, diaphragmatic tumors will be found with increased frequency. A report of this type of tumor is given in full.

The most constant symptom noted was pain in the chest, also in the hypochondrium and occasionally along the course of the regional intercostal nerves toward the shoulders. Cough was a complaint occasionally and hemoptysis, once. Bulging intercostal masses as well as masses in the right and left upper quadrants of the abdomen have been noted. Dyspnea is sometimes present and pleural effusion may occur. The diagnosis is finally made on roentgenographic evidence. Pneumoperitoneum may aid in outlining the position of the tumor.

EMIL C. ROSENBERG, M.D.

SURGERY OF THE ABDOMEN

ABDOMINAL WALL AND PERITONEUM

and F N Fundamentals of Technique in the Transverse Abdominal Incision *Surgery* 1946, 20 217

After a 30 year controversy as to the best type of parotomomy wound both the vertical and transverse approaches have stood the test of time. The author gives a detailed description of the all purpose transverse incision and answers some of the criticisms of a transverse technique.

When one or both rectus muscles are cut some filament of their nerve supply is probably sectioned. However, as this innervation is more plexiform than generally imagined and since one thoracic nerve can be sectioned without evidence of rectus paralysis clinical evidence of weakness seldom follows an incision. If the laparotomy is performed so as to visualize these nerves they can usually be spared. If nerves are cut the rectus may bulge and in the lower incision the functional integrity of the inguinal ring may be jeopardized.

If the muscle is cut across healing occurs as readily as if the rectus is split. The excellent sheathing of both sides of the muscle holds the sutures tighter when it is cut transversely and mitigates retraction of the muscle. Such an incision leaves a cosmetically insignificant scar.

The larger transverse incisions may close more easily but eversion is less likely with straining during closure than when the vertical incision is used. The expenditure of a few minutes of the surgeon's time is of no importance when considering the patient's welfare.

It has been claimed that the transverse incision does not give adequate exposure in the presence of a narrow costal angle. Adequate extension into the flanks will overcome this objection. The vertical incision is subjected to extreme strain and is difficult to close under these same circumstances.

The transverse incision should be thought of as a belt line incision being restricted to the band between the crest of the ilium and the costal cartilage. Otherwise the advantage of lateral extension into the flanks is lost. The incision should be placed an inch above or below the umbilicus. Incorrect placing of the incision has resulted in the discouragement of many surgeons trying this approach.

The technique of the low right transverse incision such as is useful for work on the appendix caecum or om is described.

1. The line of incision is selected above the brim of the pelvis just below the umbilicus.

2. The skin is incised from beyond the midline to the right flank. The external oblique muscle at the lateral end of the wound should be well exposed.

3. In the same plane as the skin incision the anterior rectus sheath is incised and extended later

ally through the aponeurotic fibers of the external oblique muscle. When the muscular portion is reached the incision turns upward slightly to split the muscle.

4. The lateral edge of the exposed rectus is lifted and the eleventh thoracic nerve or a branch of it is visualized. The muscle is then freed from the posterior sheath for a distance of 1 or 2 inches above and below the plane of the incision and retracted medially. The lower edge of the external oblique muscle is retracted downward and laterally at the lateral edge of the wound.

5. The thin sheath of the internal oblique muscle is divided next, the incision beginning at the lateral edge of the rectus sheath and extending laterally and downward in the direction of the muscle fibers.

6. The posterior rectus sheath and peritoneum are opened at the lateral margin of the sheath and the incision is extended medially almost to the midline. Lateral extension of the incision is accomplished principally by hand the internal oblique and transversalis muscles being split in the direction of their fibers. The twelfth thoracic and iliohypogastric nerves run beneath the internal oblique muscle. They should be identified and retracted laterally. The peritoneum is split laterally to the end of the wound.

7. The rectus muscles may be cut across if more exposure is necessary. The deep inferior epigastric artery and vein lying on the posterior surface of the rectus a little lateral to its center should be tied before the muscle is cut. If still more exposure is necessary the same step by step procedure is carried out on the opposite side and the patient is hyperextended. The upper abdominal incision is similar and is placed just above the umbilicus to clear the lowest portions of the thoracic cage. If the right rectus is sectioned the falciform ligament also must be divided.

The closure must be carefully planned. The medial half of the incision is closed in two layers—one for the peritoneum and posterior rectus sheath and one for the anterior rectus sheath. The lateral half is closed in three layers, namely one for the peritoneum and transversalis muscle one for the internal oblique muscle, and one for the external oblique muscle. It is well to jackknife the patient before closure is begun. Interrupted sutures are recommended but if continuous sutures are used they should be locked when the outer margin of the rectus sheath is reached. If this is not done the relatively less rigid structures in this area may lead to puckering and cause the suture to loosen. The fat and skin are closed in any rational method. Subcutaneous retention sutures do no harm but have been largely abandoned. Deeply placed retention sutures are undesirable. A narrow transverse dressing with no abdominal binder is recommended.

This incision has several advantages. It can be readily extended—a 30 inch incision from flank to flank gives unrivalled exposure with a minimum of retraction, and postoperative complications are reduced. Costal respiration is less impeded by pain spasms than in a vertical wound. Effective coughing returns sooner. Early ambulation can be accomplished with less pain. It is believed that no fundamental principles are violated by this transverse incision sited as it is in the line of the body's most important flexion crease.

ROBERT R. BIGKLOW, M.D.

GASTROINTESTINAL TRACT

Kushlan, S. D.: *Gastrointestinal Bleeding in Hereditary Hemorrhagic Telangiectasia: Historical Review and Case Report with Gastroscopic Findings and Rutin Therapy* *Gastroenterology* 1946, 7: 199.

The author traces the history of hereditary hemorrhagic telangiectasia from the time it was separated from the large group of hemorrhagic diseases of uncertain origin by Osler. The condition is uncommon although it is not rare. It is inherited as a dominant characteristic. The sexes are equally affected and either sex may transmit it although some generations may be skipped. Epistaxis beginning in childhood is often the first manifestation. Hemorrhage from the skin and oral mucous membranes is quite frequent. Gastrointestinal hemorrhages usually begin in the fourth decade. The criteria for diagnosis are definite heredity, visible telangiectases with pathological distribution and a tendency to bleed from the lesions.

The typical skin lesion is a sharply demarcated purplish red spot which may or may not be elevated. A single arterial vessel may connect with the spot, commonly called a "cherry angioma." When several branches are visible the lesion looks like an acquired vascular spider.

The basic pathology of these lesions is a thinning of the vessel walls particularly of the muscular coat which results in bulging of the wall in a defect which may be rather extensive. The lesions tend to be omnipresent in large numbers, both internally and externally, rather than in isolated groups.

The lesions are noted in the stomach and in the sigmoid colon.

Widespread bleeding from telangiectases in many different locations has been reported. It has also been reported that individual groups of dilated vessels are not permanent, but vary from time to time in number, size and tendency to bleed. Except for lowered erythrocyte count and hemoglobin values the blood findings are normal however the bleeding can result in a chronic anemia severe enough to be incapacitating and also a number of fatal hemorrhages have been reported.

Therapy has been difficult and unsatisfactory. The multitude of treatments advocated indicates the absence of any specific remedy. The only medica-

tion of proved value has been the administration of iron in full and continuous dosage to combat the anemia. A high protein diet is essential to help compensate for the chronic blood loss.

Transfusion becomes necessary in spite of the danger of reactions when the hemorrhage has been sufficiently severe or prolonged to lead to tertiary low red blood cell counts or to the danger of circulatory failure. Vitamin C had no effect on these patients. Because of the character of the lesion and the effect of vitamin P in similar situations in which other medications failed rutin which is like vitamin P in that it is a flavone glucoside was administered with excellent results. Rutin may represent a remedy for this condition and certainly in view of its nontoxicity it should be tried in this and other allied situations. EDWIN W. PAMARIZZI, M.D.

Homb, A.: *On Acute Regional Enteritis* *Acta chirurgica* 1946, 94: 343.

The author segregates cases of regional enteritis into those in which the ileum is affected, and those in which the jejunum is affected. Inflammatory processes in the upper parts of the intestinal tract run a more acute course than those in the lower parts. As to etiology it has been assumed that the inflammation is the result of infection by some microbe, but a specific bacterium has not been demonstrated. Since there is some question as to whether bacteria traverse an intact intestinal mucosa, it may be possible that irritations caused by foreign bodies such as fish bones and other gross material might initiate erosion on which inflammation can develop. The author cites a case of ulceration of the ileum by a fishbone in which the pathological changes were identical with those encountered in acute regional ileitis.

The author's material includes 33 patients with acute ileitis and 8 with acute jejunitis. The symptoms in acute ileitis were for the most part identical with those of appendicitis. One third of the patients stated that they had had previous attacks similar to the present one. The average duration of the symptoms was 24 hours, but 3 of the patients had felt slight discomfort for a period of 3 weeks. In one third of the patients the onset was sudden, while in two-thirds it was gradual. The initial symptom in most cases was pain, although no definite correlation was observed between the symptoms and the pathological findings.

Examination revealed right lower quadrant tenderness as a rather constant finding. Rigidity and tenderness on sudden release of pressure were demonstrated frequently. A palpable tumor in the right iliac fossa was found in only one patient. No parallel was found between the pathological findings and the temperature changes. Roentgenographic examination of the abdomen with a scout film was carried out in 11 patients. In 5 of these there were demonstrated the signs of peritoneal irritation i.e. small fluid levels in the ileocecal region.

The indication for operation in almost every case was suspected acute appendicitis. The findings at

Laparotomy showed exudate in the peritoneal cavity in 19 of the 33 cases. The changes in the ileum revealed injection of the serosa as a constant finding. Minor hemorrhages in the serosa were demonstrated in 8 cases, and a granulated or fibrin-coated surface was observed in 12. Most cases showed a thickening of the ileal wall with a rubberlike consistency. The lumen was constricted, but rarely to any great extent.

Interestingly enough, the author reports that although the appendix appeared normal in two-thirds of the cases, the operative treatment was as follows: appendectomy 29 cases, exploratory laparotomy 2 cases, walling off of the ileum with omentum 1 case and intestinal resection, 1 case. In the case of the last patient, it is believed that resection was unnecessary.

Postoperative follow up studies indicate that aside from a troublesome diarrhea in some instances, all of the patients recovered. These striking results might indicate that resection in most cases of regional ileitis is an unnecessary procedure.

In discussing his 8 cases of acute jejunitis the author points out that the symptoms are much more severe than in ileitis. The patients are more acutely ill and the pain occurs mostly in the epigastrium. The vomitus may be fetid and contain blood. Diarrhea is a frequent symptom with occult blood or melena, leucocytosis and the sedimentation rate usually run higher than in appendicitis or ileitis.

Seven of the 8 patients were examined roentgenographically. Rather specific findings indicative of distended, gas-containing jejunal loops with very prominent plicae were noted on the films. In the erect position the distended jejunal loops showed fluid levels.

Laparotomy was performed on 5 patients with 3 deaths due to peritonitis. Resection was not done in any instance, but the involved loop of jejunum was simply covered with omentum. Three patients were not subjected to surgery and recovered under conservative management. From these observations it would appear that resection should have been performed in the cases which ended fatally.

HAROLD LAUFMAN M.D.

Humphreys, G. H., II: An Approach to Resection of the Esophagus and Gastric Cardia. *Ann Surg.* 1946, 124, 288.

A considerable experience in dealing with tumors of the gastric cardia and the esophagus, and various older methods of dealing with these tumors are discussed. The cases of 75 patients treated at the Presbyterian Hospital, in New York, from January 1941 to January, 1946 have been reviewed.

1. Esophagectomy with cervical esophagostomy and gastrostomy (the Torek procedure). This procedure, through a right sided thoracotomy incision was carried out in 5 cases, with 80 per cent operative mortality and no cure. It is now considered justified only in lesions involving the lower cervical esophagus.

2. Esophagectomy with esophagogastrostomy lateral to the aortic arch was carried out through a left sided posterior thoracic incision in 5 cases, with 60 per cent operative mortality. One patient was well for a period of 2 years.

3. Esophagectomy with esophagogastrostomy below the aortic arch. In 9 cases this procedure was carried out through posterior thoracic incisions, and in 2 cases through an anterolateral combined abdominothoracic incision with a 45 per cent operative mortality. Two patients are well after a period of 8 and 6 months.

4. Esophagogastrastomy with intrathoracic esophagogastrostomy or esophagojejunostomy. In 2 cases operation was carried out through a posterior thoracic incision and in 10 cases through an anterolateral combined abdominothoracic incision. The operative mortality in this group was 50 per cent. Three patients are well after a period of from 5 to 15 months.

5. Partial or complete gastrectomy with intra abdominal esophagogastrostomy esophagojejunostomy or gastroenterostomy. In 3 cases the operation was carried out through a combined abdominothoracic incision, and in 2 through the abdominal portion only. There was no operative mortality. Two patients are well 2 and 2 1/2 years after operation.

6. Palliative gastrectomy. In 19 patients operation was carried out without exploration in 11 after determination of inoperability by thoracotomy and in 8 after determination of inoperability by the abdominal portion of a combined incision. The operative mortality in this group of 37 cases was 8 per cent the longest survival 30 months.

RICHARD J. BENNETT JR. M.D.

Walters, W.: Resection of Stomach. *J. Am. M. Ass.* 1946, 131, 1269.

In 3 of 5 cases in which hemorrhagic and ulcerative gastrojejunitis occurred after gastroenterostomy was performed for congenital pyloric stenosis, removal of the gastroenteric anastomosis, resection of the stomach and the Billroth I (von Haberer) type of anastomosis between the proximal end of the stomach and the duodenum produced relief. In 2 cases, hemorrhages occurred 6 and 9 years respectively after this procedure. In 1 case it followed overindulgence in food and in stimulants and gastric irritants. No further bleeding has occurred since the patient began to abstain from use of alcoholic beverages. Both patients were well when last heard from.

Two of the patients had undergone pyloroplasty after bleeding occurred without relief. Bleeding ceased after the gastroenteric anastomosis was taken down and partial gastrectomy was performed.

In 2 cases severe gastrointestinal hemorrhages apparently occurred in the presence of a relative achlorhydria.

In 1 case a gastrojejunal ulcer perforated 7 weeks following a thorough examination in which the patient was found to have a relative achlorhydria, and

findings on roentgenological examination indicated that the gastroenteric stoma was functioning normally.

In only 1 case was a definite jejunal ulcer demonstrated by roentgenological examination. In this case the patient had had definite symptoms of ulcer previously but these had responded to the medical treatment.

In the case of a naval officer operated on at the United States Naval Hospital, Philadelphia, the roentgenogram seemed to show a malfunctioning gastroenteric stoma with dilatation of the proximal part of jejunum. At operation this dilatation was not found. Excellent results have followed removal of the gastroenteric stoma and closure of the opening in the jejunum and partial gastrectomy with Billroth I (von Haberer) anastomosis.

Calneborough, H., and Slater, E. A Study of Peptic Ulcer. *Brit Med J* 1914 2: 53

A study of peptic ulcer in 130 men and 32 women was made with particular emphasis on a psychiatric examination and follow-up study for a period of 3 years.

The type of ulcer (duodenal, gastric) and the incidence are discussed. The age distribution was similar to that found in other studies. When a single married and single men were included in the group, the female group showed features of 17 to and 55 for the similar location. The effect of financial stress was believed to be slight in the males but marked in the females. An analysis of gastric disease and indigestion in parent and siblings suggested that a hereditary constitutional factor might be present.

The male patients showed a pronounced tendency to correspond to the stress and personality type. Their emotional position and their reaction to anxiety irritants, nervousness, and hypochondria was noted. The women showed a higher incidence of constitutional liability than the men. Actual neurosis was uncommon. The psychogenic cause of worry were found in 10 male and 12 female.

The results of treatment were reported as follows: relapses in one third of the patients in the first 6 months. Nine of the psychogenic cases were helpful in prognosis. Previously heavy smokers showed a lower rate of relapse presumably due to relief of smoking cessation treatment.

The authors believe that more attention should be given to the follow-up period than the post-operative work, which is a fearful and slow growth in the patient of his social and physical condition.

THE W. C. DOWLING M.D.

Houston, W. J. Aftermath of Perforated Peptic Ulcer. *Brit Med J* 1914 2: 311

The author states that the results of a survey of 100 perforated peptic ulcers in 335 cases in which the operation had been performed 12 or more years previously. On 224 patients were recorded of the 335 cases. The results were as follows: One hundred and twenty

patients reported for examination and 100 deaths in the interim were recorded.

In this hospital the rate of mortality was 15 to 1. Duodenal ulcers were more common than gastric ulcers by 2 to 1. A male to female mortality rate in 1913 a 11 to 11 to the use of self-medication.

Of the small group of patients who were questioned 33 per cent had had 1 or more operations. The number of patients who were reported for examination was 224. 6 had had recurrent symptoms.

One hundred and sixty-one patients who had duodenal ulcers were examined. Of these 100 had no further symptoms. At the time of the further symptoms had required surgery. The chances of cure were better in the small group, the rate of cure was 100 per cent. In the older age groups (45 or over) there was a comparative home diet on the recurrence of the disease.

Recurrence of symptoms was 100 per cent. The longest interval between operations was 10 years. When a patient had a relapse of symptoms for a period of 1 year or more than 1 year there was a 100 per cent recurrence in the recurrence rate.

THE W. C. DOWLING M.D.

Waucho, J. M., and Clagett, O. T. Resection of the Duodenum and Head of the Pancreas for Carcinoma. *Ann Surg* 1914 20: 331

In 10 cases resection of the head of the pancreas and duodenum was performed. The results were as follows: with an operative mortality of 20 per cent. The postoperative survival time was 10 to 100 months. The operation was done for carcinoma of the pancreas but encroachment on the duodenum was done for carcinoma of the pancreas.

Although the one large procedure was performed, it is the occasional patient who came to the hospital who would not have been operated on. The results of the operation were as follows: 10 to 100 months. The operation was done for carcinoma of the pancreas but encroachment on the duodenum was done for carcinoma of the pancreas. The results of the operation were as follows: 10 to 100 months. The operation was done for carcinoma of the pancreas but encroachment on the duodenum was done for carcinoma of the pancreas.

Therkelsen, F. J. On the Histological Pattern of Appendicitis. *Ann Surg* 1914 20: 331

The author states that the results of a survey of 100 cases of appendicitis in which the operation had been performed 12 or more years previously. On 224 patients were recorded of the 335 cases. The results were as follows: One hundred and twenty

of the swollen lymphoid tissue. Fecal particles may produce an ulceration of the mucous membrane without simultaneous obstruction and thus permit the entrance of bacteria. The noninfected ulceration may give rise to a so-called appendicitis appearing mainly in the form of a recurring or chronic appendicitis. Acute segmental appendicitis has been produced by ligation of the vessels of the organ. Therefore, embolic or thrombotic lesions of the vessels with resulting necrosis and infection due to the presence of bacteria in the lumen, may occasionally explain the sudden onset of appendicitis. In some cases trauma has been found to be the cause. The bacteria causing appendicitis are mainly *Bacillus coli* though enterococci and nonhemolytic streptococci do occur.

The author believes that it is easy to make the histological diagnosis of acute appendicitis in severe cases but in mild cases the differentiation between a normal and a pathological condition is difficult. The initial stage of acute appendicitis is a primary infection evidenced by the accumulation of neutrophilic leucocytes about a small defect in the epithelium at the bottom of a crypt. The epithelial defect is covered by a plug of leucocytes and fibrin. From this site, the inflammatory process spreads to the walls of the appendix and takes on the shape of a wedge with its base peripherally so that the leucocytes occur in largest numbers in the subserous portion. Various changes take place in the nerve apparatus of the appendix but no relationship has been established between the various changes and the different types of appendicitis.

In an attempt to establish a surer basis for the histological diagnosis of acute appendicitis the author examined 100 appendices (obtained at autopsies) of patients who died from unrelated conditions, and 199 appendices of patients who were operated upon for acute appendicitis.

A study of the normal material revealed the following:

1 In addition to eosinophils and plasma cells densely packed clusters of lymphocytes occur normally in the lymph spaces of the muscularis and subserosa.

2 Extravascular neutrophils must always be considered pathological.

3 A more or less marked fibrosis of the appendix was found in 64 per cent of the normal cases. In 25 per cent of these cases there was present a partial or complete obliteration.

4 An appendix is termed grossly normal when its surface is not particularly infected when it is not covered with fibrinous or purulent coatings and which when opened exhibits a light yellowish mucosa, which is only slightly granular, but may be the site of extensive ecchymoses. Questionable acute inflammatory changes are the thickening of the wall combined with some hyperemia of the surface and a red hyperemic mucosa which may be more or less swollen. Definite acute inflammatory changes are a distinctly congested and edematous wall, with purulent or fibrinous coating on the surface. The lumen

may be filled with pus. The mucosa is the site of necroses and ulcerations.

A study of the diseased material revealed:

1 Of 154 cases histologically proven to be acute appendicitis, only 125 revealed simultaneous gross evidence of acute inflammation. Four cases were grossly normal.

2 Two cases showed an accumulation of neutrophils in the form of small foci in the mucosa. This type is described as a localized acute appendicitis.

3 One hundred and fifty two appendices exhibited inflammatory changes extending throughout the entire organ. This type is called diffuse acute appendicitis.

4 A fibrosis of the appendix was demonstrated in 124 cases.

It is extremely difficult to make a histological diagnosis of chronic appendicitis.

SAMUEL KAJER, M.D.

LIVER, GALL BLADDER, PANCREAS AND SPLEEN

Kajser R.: Concerning Cholangiography in Compression or Stricture of the Distal Portion of the Common Bile Duct with Remarks upon the Diagnosis and Therapy of Carcinoma of the Ampulla of Vater (Über das Cholangiographische Bild bei Kompression oder Striktor des distalen Cholecholelithiasen Nebst einigen Bemerkungen über Diagnose und Therapie bei Carcinoma papillae Vateri) *Acta med scand* 1946 Supp. 170 p. 463.

The author divides his article into two parts one concerning the cholangiographic picture in a wide variety of lesions of the common bile duct, and the other being a more or less complete review of the subject of carcinoma of the ampulla of Vater including a report of 3 cases. The former part is the more interesting as it is based on an extensive experience with cholangiograms taken on the operating table in a large variety of mechanical obstructions, both intrinsic and extrinsic. In several of the films the author was able to demonstrate calculi within the duct while other types of mechanical obstruction were present simultaneously. In 1 such film there were 3 stones within the duct and between them there was a constriction which was believed to represent an organic structure caused by malignancy of the duct. In other cases there was obstruction caused by enlarged lymph glands which impinged upon the duct and narrowed its lumen. The author demonstrated a film which he believes is typical for the type of obstruction caused by fibrosis and stricture in the duct and another which is typical for the obstruction caused by carcinoma of the head of the pancreas.

In the second portion of the article the incidence, symptomatology, diagnosis, and therapy are discussed. The author is in agreement with the general literature except in regard to the reported incidence in the sexes, believing that the lesion is more frequent in the female, this is in contrast to Brunschwig's findings. The author believes that in the

clinical study there is not very much to guide one in differentiating icterus of carcinoma of the ampulla of Vater from the other more common forms of icterus. The various liver function tests may be of help in differentiation of the intrahepatic causes of jaundice. There is little, however, even at the operating table which will differentiate the ampullary neoplasm from either stricture or stone. The finding of occult blood in the stool and the roentgen study of the duodenum may be suggestive but is far from conclusive. At the operating table palpation may be of help but it is fraught with uncertainty. The probing of the duct may also be inconclusive. On the other hand the author believes that the cholangiogram is typical. The shape of the curve of the contrast medium at the lower end of the duct is not blunt as it is in stricture nor does it show a convexity upward as in the presence of a calculus but rather it plays a definite filling defect with an irregular passage.

Two cases of carcinoma of the ampulla of Vater are detailed as well as 1 of icterus secondary to hyperplastic swelling of the glands of the hepatoduodenal ligament.

WILLIAM C. BRET, M.D.

Mallet-Guy, P., Jean-Jean, R. and Rouchet J.: The Prevention of Hemorrhagic Complications in Biliary Surgery by Vitamin K. (La prévention des complications hémorragiques en chirurgie biliaire par la vitamine K.) *Lyon chir.* 1944, 4, 60.

The authors have reviewed the records of 225 patients who were subjected to surgery of the biliary tract and have made the following observations concerning the relationship of the prothrombin time and hemorrhagic tendencies.

Before operation if the prothrombin time is less than 65 per cent of normal there is risk of spontaneous hemorrhage. During operation if the prothrombin time is less than 75 per cent there is danger of difficulty in obtaining hemostasis. After operation if the prothrombin time is less than 85 per cent there is danger of hematoma formation or of hemorrhagic complications.

The 225 patients were divided into three groups.

Group 1 (63 patients) had prothrombin times higher than the minimum normal. They had no preoperative vitamin K and no postoperative bleeding.

Group 2 (126 patients) had prothrombin times which were definitely subnormal. They received vitamin K therapy until the prothrombin time returned to normal and there were no instances of postoperative hemorrhage.

Group 3 (36 patients) had prothrombin times at the lower limits of normal. They would seem to need no vitamin K, but in 3 cases a postoperative hematoma occurred. This may be due to a disturbance of the prothrombin time caused by the operative procedure. The authors believe that this group should receive preoperative vitamin K therapy and that it should be continued for several days after operation.

Thus 162 patients (a large majority of the group) had an actual or potential hemorrhagic tendency and required vitamin K therapy.

Chronic icterus was present in 87 cases. Four of these patients had neoplastic obstruction, in they had particularly low prothrombin times. However no hemorrhagic complications occurred in this group because all had received adequate vitamin K. The remainder of the patients with jaundice due to cirrhosis, hepatitis, calculus, adenopathy, cholecystitis or disturbances of the spleen or kidneys did not manifest severe disturbances of prothrombin time.

In conclusion the authors propose the following three types of treatment according to the prothrombin level:

1. An aggressive treatment when the deficit prothrombin time is at an alarming figure (50 per cent of normal or less) or when emergency surgery is necessary. Eighty drops of K thrombolytic in 24 hours with an injection of 10 mgm. of vitamin K 1, 2 or 3 days generally produces the desired effect.

2. A more leisurely treatment when the prothrombin time oscillates in the neighborhood of 75 per cent. This can be accomplished by giving 40 drops for 4 to 6 days. If there is an associated icterus one gram of bile extract should be given with every 60 drops.

3. A maintenance treatment of 40 to 60 drops in 24 hours assures continuation of the vitamin K effect during the postoperative period.

EDWARD W. GALT, M.D.

Söderlund G.: A Contribution to the Cystic and Inflammatory Pancreatic Cysts. *Acta med. scand.* 1946 Suppl. 179, p. 635.

The author reviews 3 cases of pancreatic cysts arising in connection with acute or subacute pancreatitis. All were inflammatory pseudocysts which were treated in one of two ways:

1. Marsupialization, or opening of the cyst and sewing the cyst lining to the anterior abdominal wall. With drainage thus established, shrinkage of the cystic cavity and obliteration were obtained. This method of treatment was employed in 3 of the 5 patients.

2. Gastric anastomosis. In the remaining 2 patients the cyst lay behind the stomach, firmly adherent to the posterior abdominal wall. Anastomosis of the cyst to the stomach was accomplished in these patients. The stomach was opened and an incision was made through the posterior wall directly into the cyst. The cyst lining was sutured to the stomach with closure of the anterior gastric opening to form a closed anterior drainage of the cystic contents with subsequent shrinkage and obliteration. A Welch tube where needed was employed in the anterior opening of the stomach to establish an external drainage of the contents which may be evacuated into the stomach.

The present article includes a detailed case history with daily progress notes of each patient (apparently) recorded on the original hospital chart.

STENGER A. ZIMMER, M.D.

Jameshek, W., and Grassi M H r Infectious Lymphadenosis ("Mononucleosis") and Thrombocytopenic Purpura Recovery after Splenectomy *Blood J Hemat.*, 1946 1 339

Among the features of infectious lymphadenosis ("mononucleosis") which help to distinguish it from acute lymphatic leukemia is the lack of reduction in red blood cells and platelets. Conversely the association of a well defined anemia and/or thrombocytopenia with a marked degree of lymphocytosis in which abnormal lymphocytes are conspicuous almost certainly indicates acute leukemia. The present case is an exception to this rule.

The patient was a young woman with a severe purpura hemorrhagica a generalized lymphadenopathy and a lymphocytosis. The clinical picture suggested an acute lymphatic leukemia but the lymphocytes suggested infectious mononucleosis which was confirmed by a strongly positive heterophile agglutination. When the bleeding became uncontrollable splenectomy was performed followed by prompt recovery. The splenic histology was characteristic of infectious mononucleosis.

This case is of interest not only because of its rarity but because it brings up anew the diagnostic feature of infectious mononucleosis the question of "hypersplenism" and its relationship to thrombocytopenia, and the lymphocytosis observed in a number of cases of idiopathic thrombocytopenic purpura.

SAMUEL J. FOGELSON M.D.

Smith E. B., and Custer R. P r Rupture of the Spleen in Infectious Mononucleosis. *Blood J Hemat* 1946 1 317

Infectious mononucleosis has been regarded as a benign disease until very recently. Rupture of the spleen as a fatal complication has received little attention there being only 3 well established cases in the literature. This report adds 7 additional cases in which splenic rupture occurred. All of these patients were subjected to splenectomy but only 3 recovered.

A characteristic histological picture was found in all of the patients. The splenic capsule was found to have virtually lost its identity. It was infiltrated with lymphocytes and large mononuclear cells. The capsule and the immediate subjacent pulp was edematous. The splenic trabeculae were infiltrated by mononuclear cells to an even greater degree than the capsule frequently having undergone dissolution. The splenic pulp was increased in bulk and its architectural pattern was blurred principally because of the excessively cellular curds of Billroth which compressed the sinuses and rendered them relatively bloodless. The predominant mononuclear cells varied from 12 to 15 microns and were round except when distorted by pressure. The cytoplasm was homogeneous and faintly acidophilic. The centrally or eccentrically placed nucleus was sharply delineated by a thin membrane and chromatin was irregularly distributed to lend a mottled appearance.

The blood vessels of the spleen also showed a consistently striking histological change. The small ar-

teries were ensheathed by normal and abnormal lymphocytes which completely separated them from the surrounding trabeculae. These vascular lesions are similar to those frequently found in leukemia scarlet fever occasionally in chronic malaria and acute fulminating infections.

It is obvious from these histological descriptions that the basic structure of the spleen is weakened in infectious mononucleosis, and it is surprising that it does not rupture more often.

SAMUEL J. FOGELSON M.D.

Benhamou E. and Laffargue P r Sarcomas of the Spleen (*Les sarcomes de la rate*) *Presse med* 1946 54 485

Statistics have always reported sarcoma of the spleen as being very rare but the authors have seen 9 cases in the past 6 years in Algiers which leads them to doubt its extreme rarity. Sarcoma of the spleen should be suspected if the spleen is enlarged without accompanying enlarged glands in subjects from 25 to 55 years of age, if the organ is hard and painful, if there is rapid emaciation persistent ansthenia, and irregular temperature. The diagnosis can be confirmed by the test of contraction of the spleen following the use of adrenalin and by histological examination of a smear from the spleen.

In the authors' cases there was hyperleucocytosis up to 16 000 with the proportion of the different forms of leucocytes practically normal. This served as a differential point from Banti's disease in which there is leucopenia with a tendency toward mononucleosis, from Hodgkin's disease in which the leucocytosis is predominantly eosinophilic, and from tuberculosis of the spleen in which there is sometimes an increase of the red cells.

In 5 of the authors' cases there was necrosis of the spleen with cavities resembling those of tuberculosis while in 2 other cases there was no macroscopic necrosis but necrosis was shown on microscopic examination.

Details are given in 1 case of a man of 27 who recovered after splenectomy and blood transfusion. The authors think that treatment is hopeful in these cases if the diagnosis is made early before the gland become enlarged and before the patient's general condition becomes too serious. Treatment consists of splenectomy, blood transfusion and deep roentgen therapy.

AUDREY C. MORGAN M.D.

MISCELLANEOUS

Meyer H W r Acute Superior Mesenteric Artery Thrombosis Recovery following Extensive Resection of the Small and Large Intestines. *Arch. Surg* 1946 53 293.

The author describes a case of acute superior mesenteric artery thrombosis treated by very wide resection and resulting in a good recovery. A 19 year old infantryman was recovering from minor shell fragment wounds of his left arm and right thigh in an evacuation hospital when on the third evening

after admission he developed symptoms of an acute surgical emergency. Subsequent history revealed that since 11 or 12 years of age he had been having attacks of cramplike pain several times a week to every few months which lasted a maximum of several hours. A similar attack started the day the patient was wounded but he did not mention it until the pain became unbearable. The severity of the pain was out of all proportion to the mild bilateral rectus spasm and midabdominal tenderness. The white blood count which was 17,000 at the onset of the severe attack reached 22,300 with 17 per cent stab forms and 72 per cent polymorphonuclear leucocytes by the following morning when the necessity for surgical exploration was established. At this time the patient's temperature was 100.2 F and his pulse rate 120.

At operation there was a pronounced odor of gangrene when the abdomen was opened and the presenting intestines were blue black but not distended. Gangrene extended from 20 inches distal to the proximal end of the jejunum to the midtransverse colon and when resected the thrombi were seen in the great vessels in the root of the mesentery. All of the gangrenous bowel was resected and an isoperistaltic side-to-side jejunocolostomy to the left half of the transverse colon performed. This left the proximal 13 inches of the jejunum, the left half of the

colon, and a nutritional problem seemingly without precedent.

Immediate postoperative care was essentially that of any other major abdominal procedure and surgical recovery was uneventful except for a right popliteal occlusion by a clot on the fifteenth postoperative day which was removed surgically without difficulty.

When oral feedings were started liquid stool was passed almost constantly which slowed to about 7 soft stools daily in several weeks. The urinary output was as low as between 500 and 600 c.c. daily as a result but it returned to normal in time. The stools improved until 9 months later he had 2 to 3 well formed stools daily. At this time the patient's weight was 120 pounds as contrasted with 151 pounds just before he was wounded. Throughout the postoperative period the patient's chemistry was maintained very close to normal limits. Metabolic made of high vitamin and protein intake in the immediate postoperative course but no mention is made of the intravenous and oral chloride requirements.

On all diets late in his course large amounts of fat and starch were present in the stool, but it was determined largely by trial and error that he did best on a high carbohydrate, low fat and medium protein intake.

FREDERICK C. HOWELL, M.D.

GYNECOLOGY

UTERUS

Dalgaard, J. B. The Blood Vessels of the Human Endometrium. *Acta obst. gyn. scand.* 1946 26 342

The literature on the subject of the blood vessels of the human endometrium is reviewed and a new classification of the menstrual cycle is presented.

The material consists of 16 specimens of post-mortem examined human uteri. The technique of injection is discussed. India ink was injected arterially or venously in some of the specimens in others the Sjostrand method of blood corpuscle coloration was used.

A minute description of the histological findings in every specimen is given and the material is grouped according to menstrual phases with subheadings for cervical and atrophic endometrium.

The endometrial vessels are branches and continuations of the myometrial vessels. The endometrial arteries of monkey and man are of two types, endometrial spiral arteries and endometrial basal arteries. The former arises as a continuation of the myometrial radial artery while the latter sometimes appears as a branch of the myometrial radial artery sometimes as a special vessel from the myometrium. The endometrial basal arteries supply the basal part of the endometrium, run obliquely or nearly parallel to the surface in the boundary zone but to a lesser degree in the basalis.

The endometrial spiral arteries are continuations of the myometrial radial arteries. The coils of these vessels are lowest, broadest, and present the most numerous coils per height unit in the basilar area. The author found that the endometrial spiral arteries already in the proliferative phase reach the surface, very few branches are given off. The diameters of the vessels diminish very little throughout the endometrium. They have a distinct elastic membrane. They continue directly into the venous lacunae through arteriovenous anastomoses. The lacunae are the superficial parallel network of vessels, most often seen in the phases of proliferation and early secretion. The venous plexus is interposed between the lacunae and the ordinary capillaries on one side and between the lacunae and the collecting veins on the other side.

An attempt is made to explain the anatomical findings with relation to the menstrual function.

T. FLOYD BELL, M.D.

Ritala, A. M.: On the Methods of Treatment in the Presence of Pyometra. *Acta obst. gyn. scand.*, 1946, 26 225

The author states that in Finland the majority of patients suffering from cervical carcinoma seek medical advice when suppuration has developed and the diagnosis can be made by the typical pungent

odor alone. He makes a plea for earlier diagnosis before infection has become active even though he is aware that in his country patients wait for long periods before they are admitted to the hospital.

The author gives a survey of the pathogenesis and prophylaxis of pyometra. Infection of the uterus especially in cases of carcinoma is looked upon as a local disease and even as a point of entrance for numerous inflammatory processes tending to spread throughout the body.

The possibility of using modern local antibiotics is discussed. In this connection several new instruments devised for the drainage of pyometra are described. They consist mainly of a set of graduated dilators with multiple openings. Other instruments which permit the use of wet and dry intrauterine medicaments to be introduced without increasing the intrauterine pressure are illustrated by photographs and drawings.

HARRY W. FINE, M.D.

Danforth, W. C. Total Abdominal Hysterectomy A Study of 500 Cases. *Am. J. Obst.*, 1946 52 218

In those cases in which it is preferable to perform hysterectomy by the abdominal route, total excision of the uterus is being done with greater frequency in many of the more active clinics of the country. The author believes that removal of the cervix has definite advantages whether it is accomplished by the abdominal or the vaginal route. Although the reported incidence of cancer of the cervical stump is small, it is worthy of notice. A second reason for total excision is that many of the cervixes are diseased. These cervixes which are not entirely normal are often troublesome after a subtotal operation. Therefore, elimination of the cervix seems desirable provided that it can be done without increasing the mortality or morbidity rate or in any event, an increase not greater than the number of cases of stump cancer would account for.

Danforth reports a series of 300 total abdominal hysterectomies performed by a group of trained gynecologists, all of whom are members of the Department of Obstetrics and Gynecology of Northwestern University, Chicago. The following conditions were considered essential indications for hysterectomy: myoma, cancer of the corpus, adenomyosis, and inflammatory residues. A badly diseased cervix was noted in 70 cases.

There were 2 deaths, a mortality rate of 0.4 per cent. The death of one patient resulted from septicemia; the second patient died of uremia with failure of urinary secretion, even though cystoscopy and ureteral catheterization proved the absence of ureteral obstruction.

Morbidity was estimated according to the standard of a rise of temperature to 100.4 degrees F. on any of two days, excluding the first 24 hours. Using this rigid standard 241 patients (80.3 per cent) had

after admission, he developed symptoms of an acute surgical emergency. Subsequent history revealed that since 11 or 12 years of age he had been having attacks of cramplike pain several times a week to every few months which lasted a maximum of several hours. A similar attack started the day the patient was wounded but he did not mention it until the pain became unbearable. The severity of the pain was out of all proportion to the mild bilateral rectus spasm and midabdominal tenderness. The white blood count which was 17,000 at the onset of the severe attack reached 22,300 with 17 per cent stab forms and 72 per cent polymorphonuclear leucocytes by the following morning when the necessity for surgical exploration was established. At this time the patient's temperature was 100.2 F and his pulse rate 120.

At operation there was a pronounced odor of gangrene when the abdomen was opened and the presenting intestines were blue-black but not distended. Gangrene extended from 20 inches distal to the proximal end of the jejunum to the midtransverse colon and when resected the thrombi were seen in the great vessels in the root of the mesentery. All of the gangrenous bowel was resected and so isoperistaltic side-to-side jejunocolostomy to the left half of the transverse colon performed. This left the proximal 18 inches of the jejunum, the left half of the

colon, and a nutritional problem seemingly without precedent.

Immediate postoperative care was essentially that of any other major abdominal procedure and surgical recovery was uneventful except for a right postoperative occlusion by a clot on the fifteenth postoperative day which was removed surgically without difficulty.

When oral feedings were started liquid stool was passed almost constantly which slowed to about 7 soft stools daily in several weeks. The urinary output was as low as between 500 and 600 c.c. daily as a result but it returned to normal in time. The skin improved until, 9 months later, he had 8 to 10 soft formed stools daily. At this time the patient's weight was 120 pounds as contrasted with 94 pounds just before he was wounded. Throughout the postoperative period the patient's chemistry was maintained very close to normal limits. Menstruation made of high vitamin and protein intake in the immediate postoperative course but no mention is made of the intravenous and oral chloride requirements.

On all diets late in his course large amounts of fat and starch were present in the stool, but it was determined largely by trial and error that he did best on a high carbohydrate, low fat, and medium protein intake.

FREDERICK C. HICKS, M.D.

GYNECOLOGY

UTERUS

Dalgaard J B: The Blood Vessels of the Human Endometrium. *Acta obst gyn scand* 1946 26 342

The literature on the subject of the blood vessels of the human endometrium is reviewed and a new classification of the menstrual cycle is presented.

The material consists of 16 specimens of post mortem examined human uteri. The technique of injection is discussed. India ink was injected arterially or venously in some of the specimens in others the Sjostrand method of blood corpuscle coloration was used.

A minute description of the histological findings in every specimen is given and the material is grouped according to menstrual phases with subheadings for cervical and atrophic endometrium.

The endometrial vessels are branches and continuations of the myometrial vessels. The endometrial arteries of monkey and man are of two types: endometrial spiral arteries and endometrial basal arteries. The former arises as a continuation of the myometrial radial artery while the latter sometimes appears as a branch of the myometrial radial artery sometimes as a special vessel from the myometrium. The endometrial basal arteries supply the basal part of the endometrium, run obliquely or nearly parallel to the surface in the boundary zone but to a lesser degree in the basalis.

The endometrial spiral arteries are continuations of the myometrial radial arteries. The coils of these vessels are lowest, broadest, and present the most numerous coils per height unit in the basalis area. The author found that the endometrial spiral arteries already in the proliferative phase reach the surface very few branches are given off. The diameters of the vessels diminish very little throughout the endometrium. They have a distinct elastic membrane. They continue directly into the venous lacunae through arteriovenous anastomoses. The lacunae are the superficial parallel network of vessels, most often seen in the phases of proliferation and early secretion. The venous plexus is interposed between the lacunae and the ordinary capillaries on one side and between the lacunae and the collecting veins on the other side.

An attempt is made to explain the anatomical findings with relation to the menstrual function.

T FLOYD BELL, M D

Ritola, A. M.: On the Methods of Treatment in the Presence of Pyometra. *Acta obst gyn. scand.* 1946 26 295

The author states that in Finland the majority of patients suffering from cervical carcinoma seek medical advice when suppuration has developed and the diagnosis can be made by the typical pungent

odor alone. He makes a plea for earlier diagnosis before infection has become active even though he is aware that in his country patients wait for long periods before they are admitted to the hospital.

The author gives a survey of the pathogenesis and prophylaxis of pyometra. Infection of the uterus especially in cases of carcinoma is looked upon as a local disease and even as a point of entrance for numerous inflammatory processes tending to spread throughout the body.

The possibility of using modern local antibiotics is discussed. In this connection several new instruments devised for the drainage of pyometra are described. They consist mainly of a set of graduated dilators with multiple openings. Other instruments which permit the use of wet and dry intrauterine medicaments to be introduced without increasing the intrauterine pressure are illustrated by photographs and drawings.

HARRY W FINKE, M D

Danforth W C: Total Abdominal Hysterectomy A Study of 549 Cases. *Am J Obst.*, 1946 52 218

In those cases in which it is preferable to perform hysterectomy by the abdominal route, total excision of the uterus is being done with greater frequency in many of the more active clinics of the country. The author believes that removal of the cervix has definite advantages whether it is accomplished by the abdominal or the vaginal route. Although the reported incidence of cancer of the cervical stump is small it is worthy of notice. A second reason for total excision is that many of the cervixes are diseased. These cervixes which are not entirely normal are often troublesome after a subtotal operation. Therefore elimination of the cervix seems desirable provided that it can be done without increasing the mortality or morbidity rate or in any event an increase not greater than the number of cases of stump cancer would account for.

Danforth reports a series of 300 total abdominal hysterectomies performed by a group of trained gynecologists all of whom are members of the Department of Obstetrics and Gynecology of Northwestern University Chicago. The following conditions were considered essential indications for hysterectomy: myoma, cancer of the corpus, adenomyosis and inflammatory residues. A badly diseased cervix was noted in 70 cases.

There were 2 deaths a mortality rate of 0.4 per cent. The death of one patient resulted from septicemia, the second patient died of uremia with failure of urinary secretion, even though cystoscopy and ureteral catheterization proved the absence of ureteral obstruction.

Morbidity was estimated according to the standard of a rise of temperature to 100.4 degrees F on any of two days, excluding the first 24 hours. Using this rigid standard 241 patients (80.3 per cent) had

a morbid recovery. Serious morbidity occurred only rarely. Thrombophlebitis occurred in 3 cases, all 3 patients recovered. Ureteral injury occurred in two instances and nephrectomy was necessary in both cases. In 4 cases the bladder was opened. Immediate suture plus the use of a permanent catheter yielded a smooth recovery.

The adnexa were treated conservatively unless gross disease was present. The author prefers to leave the appendix alone.

The simple technique is well described and amply illustrated. Fine chromic catgut is used and closure is accomplished without drainage. The author believes that in trained hands total abdominal hysterectomy may be used frequently or even almost routinely.

EDWARD L. CORVILL, M.D.

Heyman, J., and Benner, S.: Further Experience with Radiotherapy in Cancer of the Corpus of the Uterus. *Acta radiol. Stockh.* 1945, 27, 318.

The 5 year results in cases of cancer of the corpus of the uterus treated from 1934 to 1939 by the Radiumhemmet method of packing the uterine cavity with radium tubes is reported. The survey of the results is preceded by a brief summary of the classification, examination, and treatment.

Prior to 1930, cases of corpus cancer were treated by introducing into the uterine cavity a single tube containing between 35 and 45 mgm. of radium element. The patient was irradiated twice with an interval of 3 weeks between the first and the second treatment. Each time about 1,500 mgm. of unsatisfactory results obtained by using a single narrow and powerful tube the packing method was gradually elaborated between 1930 and 1934 and now the uterus is packed with less powerful tubes of equal size and shape and in sufficient numbers to get the uterine cavity completely filled.

Primary radiological treatment combined with surgery in case of failure is the routine method of treatment. Primary surgical interference is resorted to in occasional operable cases, for instance cases of corpus cancer combined with large fibroids or with an ovarian tumor. In each case, radium is applied twice with an interval of 3 weeks between the irradiations. The time during which the radium remains in the uterus varies with the number of filters chosen. The treatment time is given in a table at the end of the original article.

During the period from 1934 to 1939, inclusive, 693 patients suffering from cancer of the corpus were seen. In 28 cases, treatment was considered unsuitable. A 5 year cure rate of 64.9 per cent was obtained by the packing method in a series of 316 patients treated compared with 45 per cent in 354 patients treated with a single tube. The authors believe that it is possible to obtain better results by radiotherapy alone than by surgery alone. Following the use of the packing method, 22 patients were operated upon after failure of radiotherapy.

Conclusions as to the value of primary hysterectomy plus postoperative irradiation, compared with that of primary radiotherapy plus hysterectomy in case of failure of the former, should be postponed until significant statements concerning the results of the first mentioned method are available.

GROENIE BURCK, M.D.

Kahan, J. L.: Carcinoma of the Cervix Uteri in Young Women. *Acta obst. gynaecol.* 1945, 24, 379.

The author's material consists of 28 cases of carcinoma of the cervix uteri in patients under 30 years of age, the youngest being 21 years. The statement that carcinoma of the cervix is being transferred to younger age groups has not been proved and seems improbable. The lack of pregnancy in the previous history does not exclude the possibility of the disease in a young woman.

The possibility that carcinoma of the cervix is general is especially malignant in young women does not seem likely. As judged from the results of treatment. The author recommends local examination of young women which will avoid treatment at a late stage with its bad prognosis. The possibility of carcinoma in a young woman should always be considered in the event of irregular bleeding, and a kind of treatment suggested until examination has ruled out cancer.

T. FLOYD BELL, M.D.

Ritola, A. M.: Clinical Investigation of a Complication: Fistula Rectovaginalis after Radium Therapy of Cervical Carcinoma. *Acta obst. gynaecol.* 1945, 25, 93.

During the past 20 years at the Women's Clinic of the University of Helsinki, almost 2,000 patients have been treated with radium for cancer of the cervix. This was done by the so-called Stockholm method in which the cervical or intrauterine dose is generally 2,400 mgm. hr. and 4,500 mgm. hr. respectively. Most of the patients, unfortunately do not present themselves for treatment until they are in group III or IV. There were 331 cases of grades I and II which received radium treatment. Only these cases were used as suitable material for investigation of the occurrence of rectovaginal and rectovaginal fistulas following radium treatment since in cases of grades III and IV the malignancy itself may have affected the surrounding tissues to the point of perforation.

In nearly one-half of the patients treated by radium in the usual way there developed symptoms of irritation: tenesmus, ulceration, accompanied by hemorrhages, and frequently also stenosis in the rectum caused by induration. There were 8 cases of rectovaginal fistula. During the first 10 year period there were none and then 5 developed from 6 to 13 months after the irradiation. The perforation of the rectovaginal septum caused a long period of suffering, an inflammation of the rectum higher up led to general peritonitis and a hasty end.

Since the avoidance of injury to the rectum and the bladder is the central feature in radium treatment in gynecology the author discusses the problem of the advisability of increasing the present vaginal dose of between 4,500 and 5,000 mgm. hr in order to obtain better end results in the treatment of cancer and at the same time diminish the danger of injury to neighboring organs, especially the rectum. He has come to the conclusion that this is possible.

HARRY W. FINE, M.D.

ADNEXAL AND PERIUTERINE CONDITIONS

Bohm E., and Englund, S: Results of Salpingostomy at the Public Maternity Hospital Stockholm, 1931-1942. *Acta obst gyn scand* 1946 16 379.

Martin in 1885 was the first to carry out a salpingostomy. Since then many reports have been given with varying results. The author reviews these reports. American gynecologists were mainly opposed to the operation because of the bad results obtained. According to the more comprehensive collection of material cited from 7 to 10 per cent of the cases operated upon resulted in pregnancy and the number of parturition pregnancies varied between 3 and 8 per cent.

The indications for salpingostomy are enumerated. In general they embrace chiefly cases with slight changes and only exceptionally those with more serious changes.

The material presented embraces 64 salpingostomies resulting in 3 cases of parturition 4 ectopic pregnancies and 1 abortion.

T. FLOYD BELL, M.D.

EXTERNAL GENITALIA

Paracchi, P: Carcinoma of the Clitoris (II carcinoma del clitoride). *Tumori Milano*, 1943 28 102.

Meyer (in 1868) was the first to describe carcinoma of the clitoris as an entity. Reports of other cases followed so that up to the present time 358 cases of primary carcinoma of the clitoris have appeared in the literature. To these the author adds all cases treated in the Gynecological Section of the Istituto Nazionale Vittorio Emanuele, in Milan, Italy from May 1 1928 to April 30 1944 i.e., 12 cases of primary carcinoma of the clitoris, 21 cases of carcinoma of the external genitalia with involvement of the clitoris which was no longer recognizable anatomically and 6 cases in which carcinoma of the clitoris was metastatic from a primary uterine neoplasm. From his observations he comes to the following conclusions:

1. Carcinoma of the clitoris is not so rare when considered in relation to carcinoma involving the external genitalia. Of 3116 cases of malignant tumors of the female genital organs treated in this Institute since its inception, 96 showed involvement of the external genitalia and of these, 39 (40.6%) had involvement of the clitoris.

2. In most of the cases the condition occurred between the sixtieth to sixty fifth years of life. It occurs only rarely in the young.

3. The average beginning of menstruation was at 14 years and 1 month. In only 1 patient had menstruation started at the late age of 28 years.

4. Sexual relations are not considered an etiological factor.

5. Pregnancy and dystocia must be disregarded as a cause. Instrumentation at the time of delivery involves the vaginal fourchette, and this is not the primary location of the neoplasm. Two patients in whom the primary carcinoma was located in the posterior commissure were nulliparous.

6. The disease is more frequent in women who have had an early menopause.

7. Leucoplakia and kraurosis vulvae must not be considered a precancerous condition its presence is only coincidental. It takes some imagination to conceive of a leucoplastic cell all at once becoming aggressive proliferative disorderly anarcho- in one word a cancer cell. The ovary plays no part in the etiology of primary carcinoma of the clitoris which occurs in old age and many years after the menopause. Smegma hidden under the prepuce of the clitoris may have to be considered a factor.

The clitoris anatomically consists of the body made up of erectile tissue as is the penis (the corpora cavernosa being surrounded by a tunica albuginea 1 mm. thick) and the gland made up of squamous epithelium and capped by the prepuce which is rich in glandular tissue. Therefore, in the clitoris 3 types of tumor may take place epithelioma sarcoma, and melanotic tumors.

The epithelioma originates from the squamous epithelioma of the gland and may be the (1) spinal cell type (55% of the cases) with hyperchromatic polygonal cells and more or less keratinization the (2) basal cell type (36% of cases) characterized by much mitosis and atypicity of cells the oblong nuclei being hyperchromatic and karyokinesis frequent the (3) basal spinal cell type (9% of cases), the (4) adenocarcinoma, a rare type made up histologically of nests of cells surrounding a central cavity and arranged like the lobes of an acinous gland.

The sarcoma is rare originates from the connective vascular tissue and is characterized by numerous young cells with atypical mitosis. This tumor is very vascular. No cases of sarcoma were found in the author's material.

The melanoma is rare. Frank has stated that pigmented malignant tumors of the external genitalia constitute 3 per cent of all pigmented tumors. The tumor varies in size from that of a pea to a hen's egg and tends to metastasize to distant parts of the body.

Tumors of the clitoris may assume any of the following forms:

Vegitative—cauliflower like with a base either sessile or pedunculated bleeds easily. In the author's material 45 per cent of the cases were of this type. The lesion remains localized for a long time.

Ulcerative—craterlike with indurated edges and a vegetative bottom covered with sanguineous fluid (made up 40 per cent of cases). In advanced cases it will destroy the clitoris completely.

Infiltrative—tends to invade all tissues around it to such an extent as to obliterate the primary location (made up 15 per cent of cases). In 1 case the ischiopubic ramus was invaded.

In carcinoma of the clitoris the anatomy of the lymphatic drainage must be kept in mind, i.e., the lymphatics of the corpus clitoris end in the superficial lymphatic glands, while the lymphatics of the gland empty into the iliac glands by way of the inguinal ring or femoral canal and knowledge of this fact helps in the diagnosis and also determines the treatment. Neither should one forget that enlarged glands may be inflammatory and not a metastasis from a cancerous growth.

The most common symptoms are pruritus in the area of the clitoris, burning sensation of the vulva, and some slight pain in the inguinal region and legs occasionally hemorrhage may complicate ulceration. One of the author's patients developed a massive regional adenopathy followed by ulceration and a massive hemorrhage that killed the patient. The diagnosis is not difficult. In the ulcerative type luetic ulcer and tuberculous ulcer must be differentiated. The final diagnosis rests on biopsy and microscopic examinations.

The prognosis is always guarded. Without surgical intervention life may continue from 1 to 5 years. Three patients (75%) recovered completely 5 are living and well 10 years after operation 5 are living 3 years after operation 1 patient is living 5 years and 3 patients, 1 year after operation. Four patients failed to report so died the first year 6 died the second year and 1 died the fourth year after operation.

Basset and Taussing advise a two-stage operation i.e., removal of the inguinal gland at the first stage, and vulvectomy at the second stage. Whenever feasible, the author has performed a one-stage operation followed by radium and x ray therapy.

MISCELLANEOUS

Grux, H.: Surgery for Female Sterility (*Cirugía de la esterilidad femenina*). Arch. Soc. cir. hosp. Santiago, 1946 6 227

The author enumerates the etiological factors involved in sterility and the means necessary to correct them. Thorough examination of both partners, male and female, should always be done, each being considered equally responsible for the sterility until the exact cause is ascertained. The contributing factors are grouped into five classes:

1 Genital lesions which may be irreconcilable with fecundation these should have careful gynecological correction.

2 Cervical secretion hostile to the semen and in semination through the uterus.

3 Tubal pathosis which either partially or completely occludes the orifice.

4. Endocrine hormonal dysfunction which manifests itself in anomalies of the menstrual cycle and ovarian malfunction this can be determined by endometrial biopsy.

5 Sterility in the male partner. This necessitates complete semen examination.

A complete physical examination in order to ascertain the presence of any general systemic disorder such as syphilis or tuberculosis is necessary.

The genital lesions which cause sterility include genital malformations such as intact, rigid, or imperforated hymen, vaginal atresia or occlusion, a total or partial absence of the vagina, bicornual vaginal septa and bicornuate uterus.

Malposition of the uterus such as retroversion and retroflexion contributes to endocrine ovarian dysfunction which results either in reduction of the total number of ova or production of imperfect ova, or the development of an abnormal endometrium which prevents proper implantation.

Coexisting with retrodisplacement of the uterus may be such conditions as occlusion or constriction of the tubes, congestion and hyperplasia tending toward endosalpingitis, decreased resistance of the pelvic organs to infection, and endometriosis. Anfibosion may also cause stenosis of the internal os and in this manner prevent fecundation.

Myoma of the uterus has no absolute relation to sterility. When found, however investigation should look beyond the myomatosis for cause of the sterility. However sterility may result from mechanical occlusion or compression of the tubal organs, especially when there is endocrine dysfunction or coexisting inflammation of the tubes.

Various techniques of surgical treatment of uterine myomas are described.

Ovarian tumors are in themselves no barrier to pregnancy. The number of complications these tumors produce during pregnancy clearly demonstrates this point. The effect of ovarian cysts on sterility is an open question various authors cite percentages ranging from 6 to 17 per cent. The manner in which the sterility is produced is also in doubt. The surgical treatment of ovarian cysts need not require sacrifice of the ovary: various operative techniques are presented illustrating this point.

Inflammatory pelvic lesions constitute the most common cause of sterility in women, gonorrhea being the most frequent offender. Tubal tuberculosis, however, should receive special consideration for its surgical management permits of no conservation in treatment.

There are a cervical conditions inimical to fecundation: secretion of substances hostile to the spermatozoa, and closure of the cervical canal. These may be brought about by an endocervicitis, cervical polyp or stenosis of the external os, and must have appropriate treatment before pregnancy can be expected.

Affections of the tube account for 47 per cent of the sterility in women, the most frequent cause being

gonococcal infections and subclinical tuberculous salpingitis. These contribute to ectopic pregnancy.

Insufflation according to the Rubin technique is considered most useful in the diagnosis of the condition of the tubes as well as being a therapeutic aid in correcting tubal obstruction under certain conditions. The indications and contraindications for hysterosalpingography are given. Surgical correction of tubal obstruction consists in salpingolysis, salpingostomy, resection of the isthmus with end-to-end anastomosis, implantation of the tubes into the uterus, transplantation of the tubal horn or transplantation of the ovary into the uterus.

Endocrine dysfunction accounts for 15 per cent of the sterility in women. Suppression of ovarian function is primary and is brought about by some pituitary ovarian imbalance. There is insufficient secretion for inducing ovulation or luteinization or a postinflammatory fibrosis may exist which prevents normal secretion from causing follicular rupture. Polycystic disease follows and surgical methods are usually resorted to for relief.

The masculine element of sterility calls for complete examination of the semen among other factors but the author abstains from enlarging on this point as he considers it beyond the scope of his present theme.

STEVEN A. ZIEGAN, M.D.

Peril, H.: The Treatment of Functional Traumatic Bladder Incontinence and Vesicovaginal Fistula at the Allmänna BB (Über die Behandlung der funktionellen traumatischen Blaseninkontinenz und der vesicovaginalen Fisteln in d. Allmänna BB). *Acta Obst. Gyn. scand.*, 1946, 25, 547.

Nineteen cases of women with functional bladder incontinence and 10 with vesicovaginal fistula are reported. Of the 19 patients, 16 exhibited a relative incontinence, that is the urine loss would occur only under special circumstances (heavy lifting, stooping, coughing, laughing), and 3 an absolute incontinence. In 1 instance there was evidence of diabetes insipidus which was, however, interpreted as a relative incontinence. Seventeen of these women had borne children, and in 9 of these the incontinence appeared immediately following the delivery. Of the 9, 6 had had a spontaneous delivery in 3 forceps were used and the remaining patient had undergone extraction of a pelvic presentation. In 4 of the remaining 8 patients, in whom the incontinence had developed gradually in the course of from 5 to 15 years following childbirth, the condition appeared coincidentally with a prolapsus vaginae, and in the other 4 no immediate cause could be found. In 1 of the 3 women who had not borne children the condition appeared following emptying of the uterus, and in the other there was a retroverted myomatous uterus which appeared to have drawn the cervix up behind the symphysis.

Of the 10 cases of fistula, 8 had followed childbirth, with a long period of labor and with large children. In 1 of these 8 the delivery was spontaneous and in 6 obstetrical operations were carried out (3 forceps

deliveries, 2 perforations with extraction and 1 extraction of a pelvic presentation). Of the 3 remaining patients who had not borne children, 1 had been subjected to extirpation of the uterus following radium therapy and the other had had a paraurethral abscess (urethral fistula).

In 17 of the 19 cases of functional incontinence an anterior colporrhaphy was done and in 13 of these the suture line was reinforced by a muscle plastic operation on the urogenital trigonum or pelvic diaphragm and/or plication or overlapping of the connective tissue of the bladder. The immediate results were good, that is, the involuntary loss of urine was stopped or as good as stopped, in 78.4 per cent of the cases. However, the answers to follow up letters of those who responded indicated that there was permanent healing in only 54.5 per cent, while the incontinence had recurred in 45.5 per cent, although in no case was it as great as it had been previously. The author believes that the surgeon may be somewhat to blame for these results in that he does not give the patient sufficient instructions for the postoperative period. The patient should not do any heavy work, should not have coitus, and should not even be examined vaginally or have a catheter passed for a period of at least 3 months following the operative repair.

None of the 10 fistulas was firmly adherent to the bony structures of the pelvis and this must be considered as indicating an especially favorable condition for surgery. Seven of these patients were operated upon according to the method of Faeth, or of Ferguson-Brasche-Faeth, with closure of the fistula in all. In one of these 7 a preliminary supra-symphysal fistula was created. In 2 of these 7 cases there was a concurrent urethral defect. In 1 of these 2 the fistula was first closed by the method of Faeth as mentioned and then at a second operation a new sphincter was formed from the pars publica levatoris muscle with satisfactory control of the urine. In the other case the urogenital diaphragm was used to reinforce the urethral defect, however the fistula recurred to a certain extent. In 1 case complete continence was obtained by overlapping with the levator ani muscles and 3 cases must be considered as failures, although the fistulas closed spontaneously at a later date. In 1 of these 2 failures in a very corpulent woman section was first done and a suprapubic fistula created, then the bladder mucosa was freed and stitched transversally, this was followed by continued suture of the paravascular connective tissues. However a month later the incontinence had recurred and at the second operation the fistula was again carefully repaired. In a few days the condition had recurred in its original location and to the same extent. The patient was later treated repeatedly for infection of the bladder and stone formation and the fistula finally closed of itself and some degree of urinary control developed. In the second case of failure, 3 operations of repair failed, but the fistula closed later of itself nevertheless the incontinence continued.

JOHN W. BRENNAN, M.D.

Stanley M M: Gonococcal Peritonitis of the Upper Part of the Abdomen in Young Women (Phrenic Reaction, or Subcostal Syndrome of Stajano; Fitz-Hugh-Curtis Syndrome): Report of Cases of 3 Patients Treated Successfully with Penicillin and Summary of Literature *Arch. Int. M.*, 1946, 78: 1

Peritonitis of the upper part of the abdomen in young women occurring during the course of gonorrhea was first described as a definite syndrome in 1919 by Carlos Stajano. In 1930 Curtis called attention to the frequent coexistence of gonococcal salpingitis and "violin string" adhesions between the anterior surface of the liver and the anterior abdominal wall discovered at operation, conditions indicating presumably a chronic, healing, or healed perihepatitis. Fitz-Hugh, in 1934, described 3 cases in the acute stage. Since then numerous articles have appeared in the literature, and the clinical entity has been well documented.

The purpose of this article is to report 3 typical cases of gonococcal perihepatitis. All 3 patients were treated with penicillin and recovered rapidly.

Invariably women in whom the syndrome develops have had an antecedent gonococcal infection, sometimes as much as 5 years previously. Often it will be impossible to elicit the usual symptoms of gonorrhea. However, on direct questioning a history will frequently be revealed of menorrhagia or dysmenorrhea, burning on urination, vaginal discharge, or vague pain in the lower part of the abdomen during the few days or weeks preceding the occurrence of frank symptoms of peritonitis.

The onset is usually dramatic. There is the sudden occurrence of excruciating sharp pain in the upper part of the abdomen, usually on the right side, most intense anteriorly under the rib margins and often referred to the top of the corresponding shoulder. It is of the "pleuritic" type, exaggerated by deep breathing, coughing, laughing, and by movements of the trunk. Hiccup may be troublesome. Nausea is of frequent occurrence, but vomiting follows less often. When symptoms are present in the lower part of the abdomen they are usually worse on the side of the phrenic reaction, but they are usually overshadowed by the more acute process in the upper part of the abdomen.

It has been repeatedly recognized that trauma to inflamed pelvic organs in the form of surgical procedures, gynecological examination, intercourse, or douching may precipitate the development of this complication. One of the most frequently observed types of reaction in the experience of Stajano was the postoperative variety.

The physical examination discloses an acutely ill but not prostrated patient. The temperature is usually somewhat elevated, although rarely above 103°F. There is pronounced tenderness and muscular spasm at the site of greatest intensity of the pain, usually in the right upper abdominal quadrant, which indicates an underlying peritoneal inflammatory process. Occasionally a friction rub is heard.

The suspicion of preceding gonorrhea aroused by the finding of slight or moderate tenderness in the lower part of the abdomen is confirmed when other evidences of gonococcal infection—inflammation of Skene's glands or the glands of Bartholin, urethritis, cervicitis, or salpingitis—are discovered. Small pleural effusions, confirmed by the aspiration of small quantities of fluid, are not uncommon.

Other stigmas of gonococcal infection, and such as arthritis, tenosynovitis, or keratitis blennorrhagica, may be present.

Culture of the cervical or urethral secretions under proper conditions invariably yields gonococci. The observation is often not confirmed by the examination of stained smears, no matter how painstakingly carried out. Leucocytosis is the rule, although the total count is usually not elevated above 15,000 white cells per cubic millimeter of blood. A very slight, transient elevation of the bilirubin content of the blood may be found. A slightly icteric tinge has been noted. Duodenal drainages were performed in 18 patients in one series with uniformly negative results.

Roentgenological visualization of the gall bladder by means of radiopaque dye reveals a normally functioning organ, without stones, in nearly every instance. A nonfilling gall bladder may occasionally be found.

The roentgenogram of the chest is usually normal except for some elevation of the diaphragm on the affected side.

Although gonococci have not actually been cultured from material taken directly from the subphrenic space at operation, there can be little doubt that they are present. Localized, fairly dry peritonitis involving the anterior surface and edge of the liver, the adjacent peritoneal surface of the diaphragm, and the anterior abdominal wall has been noted. The peritoneum in these areas was injected and had the appearance of salt sprinkled on a moist surface. Presumably this acute inflammatory reaction subsides in a few weeks and leaves the "violin string" adhesions in the same location.

There appears to be almost no tendency toward abscess formation in the subdiaphragmatic space following its invasion by the gonococcus.

The route of extension of the infection from the pelvis to the subphrenic spaces, whether via the paracolic gutter or through the retroperitoneal lymphatics, is in doubt. Definitely in some instances, there is direct extension rather than metastasis.

When one is presented with the clinical picture previously described, especially in a young woman, the diagnosis can be made with a high degree of certainty by merely establishing the presence of gonococci in the urethra or cervix. This decision should be made on the basis of culture, and not of smears alone.

The most frequently encountered diagnostic problem is the differentiation of gonococcal peritonitis from acute cholecystitis. Other abdominal conditions from which this disease must be differentiated

include ruptured peptic ulcer, appendicitis with subphrenic abscess, and other forms of peritonitis.

An accurate diagnosis is important, especially in ruling out those diseases requiring surgical intervention, for not only is such interference unnecessary but it may actually be harmful.

There have been no deaths reported as resulting from this type of gonococcal peritonitis. The usual course when it is untreated is slow subsidence of the acute pain to a dull ache which gradually disappears the whole process requiring from 1 to 4 weeks.

At the present time penicillin is the drug of choice with doses of 30,000 units administered every 3 hours intramuscularly there is almost complete relief of symptoms after 24 hours of treatment.

Three typical cases of gonococcal peritonitis treated by penicillin are reported by the author.

DANIEL G. MORTON, M.D.

Clotti, R. Umbilical Metastases from Tumors of the Female Genitalia. (Metastasi ombelicali da tumori dell'apparato genitale femminile) *Riv Ital Ginec.*, 1944, 27, 107.

Skin metastases are very rare in malignant tumors, especially in those of the female genitalia. No accurate statistics as to their frequency can be collected from the literature.

The author describes 2 cases of metastasis to the umbilicus. The first was in a woman of 56 who was operated on May 12, 1941 for an adenocarcinoma of the right ovary with extensive adhesions to the omentum and ascending colon. The laparotomy incision did not reach the umbilicus. The patient was readmitted to the hospital March 13, 1942. She was still in good general health with normal genital findings but the base of the umbilicus was ulcerated and the ulceration was covered with a reddish fungoid growth which bled easily. Fragments removed from the umbilical region showed the same structure as that of

the primary tumor. She was given radium treatment and discharged from the hospital March 28. She is still living.

The second case was in a woman of 59. Curettage of the uterus February 13, 1941 showed adenocarcinoma of the body. The patient objected to operation and was given roentgen radium treatment and discharged on May 20, 1941. She was readmitted February 17, 1942 and reported that a small dark red nodule had been developing in the umbilicus for about 2 months. The nodule was the size of a cherry and surrounded by normal skin but the surrounding tissue was infiltrated. Examination of a biopsy specimen showed the same structure as that of the primary tumor. Roentgen and radium treatment was given and the patient was discharged with the lesion almost entirely epithelialized. She died later however in another hospital.

In the first case the adhesions indicated that diffusion of the tumor to the abdominal cavity had already taken place at the time of the operation. From the parietal peritoneum the cells had passed by continuity to the skin following either the interstices of the tissues or the local lymphatic spaces.

In the second case the tumor had apparently not invaded the abdominal peritoneum. However when the patient was readmitted after a year in poor general condition, the liver was enlarged and it is probable that the tumor had diffused along the lymphatics of the falciform ligament and those of the round ligament and reached the skin. On the other hand it is possible that the lumbocortic lymph glands first became involved and that the process extended from there to the lymph glands of the liver secondarily or the tumor may have extended through the lymph glands of the urachus to the umbilicus and then to the liver. These skin metastases do not take place through the blood circulation.

AUDREY G. MORROW, M.D.

OBSTETRICS

PREGNANCY AND ITS COMPLICATIONS

Newton, W. H., Theobald G. W. and Nixon, W. G.
W : Discussion on Water Metabolism in Pregnancy. *Proc. R. Soc. M. Lond.*, 1946, 39, 518.

W. H. NEWTON. The speaker first reviews briefly the general principles involved in the distribution of water in the blood stream, the interstitial spaces and the cells, and then analyzes the situation occurring during pregnancy. Various balance experiments indicate that during the latter part of pregnancy about 3 gm. of sodium are retained weekly. If this were all osmotically active it would require the storage of about 1 liter of water weekly to dilute it, but as this does not occur it must be assumed that all of the sodium does not exert osmotic pressure. With the increase in plasma volume there may be a decrease in plasma protein which in turn decreases the osmotic pressure in the blood stream and alters the fluid exchange. The legs constitute 37 per cent of the body weight, and the three fold increase in venous pressure in the lower extremities during pregnancy tends to force water out into the tissues. This may be counterbalanced by increased tissue pressure.

G. W. THEOBALD. The fluid balance in the body is ultimately controlled by the kidney but certain factors may interfere particularly during pregnancy. The increased blood volume may be compensatory for the increased vascular bed. Dilution of the blood decreases the effective osmotic pressure of the plasma proteins and therefore the protein intake should be high during pregnancy. Increased amounts of sex steroids are responsible for electrolyte retention during pregnancy and thus, likewise for water retention. Probably all of the sodium is not osmotically active since not enough water can be accounted for if this were true. The average weight increase is about 24 pounds, but estimates of the total nitrogen retention show an average of about 1 pound which is equal to 6 pounds of protein or 30 pounds of new tissue. Since this does not occur it seems obvious that much of the nitrogen is stored as such. Some of the weight increase is due to water retention since edema occurs and since so much water is lost rapidly after delivery. Weight gains which are significant in indicating water retention are sudden gains late in pregnancy. A slow increase over a long period of time is less significant. Excretion of ingested fluid during pregnancy is delayed with the patient in an upright position, therefore bed rest is the best position for the patient in whom there is abnormal fluid retention.

W. C. W. NIXON. Edema is the main clinical evidence of abnormal water metabolism. Pregnancy added to a deficiency state may be associated with edema. This is particularly true in the lack of vitamin B₁. Vulvar edema may be due to protein deficiency. The mechanism of edema is not always understood. Edema is affected by posture, therefore the feet and

hands are common sites for the condition. This disappears when the individual lies down. Treatment depends upon the elimination of salt and water for the more severe cases (the fluid intake should be restricted) and the patients given hypertonic glucose solutions intravenously. Plasma may likewise be used.
J. ROBERT WILLIAMS, M.D.

Moscoso, C. J. : Large Ovarian Cysts with Torsion of the Pedicle Complicated by Pregnancy (Grandes quistes de ovario con torsión de pedículo embarazado). *Obst. gín. lat. amer. B. Abt.* 1946, 4, 6.

This article relates the fundamentals necessary in diagnosis of an ovarian cyst in the presence of pregnancy, the necessity of distinguishing it from tumors of the liver, bladder, pancreas, mesentery and intestines, and the symptomatology when a twisted pedicle has occurred. The last depends upon whether or not the torsion is acute or chronic. If acute, three forms are possible: (1) cases in which there is internal hemorrhage with symptoms of acute anemia and rupture of the viscus; (2) cases in which there is peritonitis, with pain, distention, rigidity, shock, and vomiting; and (3) cases in which there is mechanical obstruction, with symptoms of intestinal obstruction.

The case histories of 3 pregnant patients are presented, each of whom had a right ovarian cyst with a twisted pedicle.

At operation the tumor in the first patient was found to lie transversely and adjacent to the liver and that in the second patient fell over to the left side adjacent to the splenic flexure. Both tumors were removed without any disturbance of the subsequent course of gestation.

In the discussion of this rare affection it is thought that pregnancy predisposes to torsion, and when torsion is observed immediate operation is indicated.

STEFANO A. ZINCA, M.D.

Macalfee, C. H. G., Phillips, L., Barnes, J. Young, J. and Others : Discussion on Placenta Previa. *Proc. R. Soc. M. Lond.*, 1944, 39, 531.

C. H. G. MACAFEE. Since 1937 191 cases of placenta previa have been cared for by one staff member of the Belfast Royal Maternity Hospital. The maternal mortality was 0.52 per cent and the corrected fetal mortality 18.6 per cent. Since the main cause of fetal mortality associated with placenta previa is prematurity, carrying the patient as near term as possible will reduce this rate. This can be done safely if the patient is watched in the hospital as the initial hemorrhage is rarely profuse. Eventually vaginal examination was carried out after all preparations had been made to deliver the patient, in order to determine the type of placenta previa so that an adequate plan of treatment could be outlined.

L. PHILLIPS. In 139 cases of placenta previa treated at Queen Charlotte's Hospital prior to 1933, the maternal mortality rate was 6.47 per cent and the fetal mortality 52.5 per cent. In the next 143 cases the maternal mortality was 1.4 per cent and the fetal mortality 58.7 per cent. The factors responsible for the reduction in maternal mortality were (1) the better condition of the patients on admission, (2) the increased use of blood transfusion, (3) the extended scope of cesarean section, and (4) the team work among the obstetrician, the resident staff, and the nurses. All cases were examined under anesthesia to determine the type of placenta previa. In those in which the os was completely covered or in primigravida with a long closed cervix, cesarean section was done. In incomplete placenta previa the membranes were ruptured in vertex positions and a foot was pulled down in the breeches. If bleeding continued vaginal tamponade was done. The mistakes that might have increased the mortality were (1) immediate examination in all cases which increased the fetal mortality (2) failure to have preparations made for cesarean section, (3) the use of dilators if the cervix was closed and (4) plugging of the vagina.

J. BARNES. In 140 cases of placenta previa the maternal mortality was 2.9 per cent and the fetal mortality was 55.2 per cent. Of the 71 infants lost, 38 died after a leg had been pulled down to control hemorrhage, prematurity and intrapartum asphyxia were major factors in infant deaths. Of the 4 maternal deaths 1 followed hemorrhage associated with bougie induction, 1 was due to pulmonary embolism on the seventeenth day, 1 was due to shock, and the fourth was due to septicemia. It is recommended that all patients be treated in a maternity hospital so that sepsis can be avoided and blood be available. Patients should be treated expectantly without vaginal examination in the absence of severe hemorrhage.

J. YOUNG. In 108 cases the total fetal mortality was 19.4 per cent during the first 6 years of the 10 year study the infant mortality was 29.8 per cent and in the last years 13.4 per cent. In 33 cases treated expectantly the fetal death rate was 9 per cent.

M. KERR. For the most part treatment of placenta previa should consist of rupture of the membranes for the less severe cases and cesarean section for the rest.

A. W. PURDIE. In 143 cases treated at the North Middlesex County Hospital there was 1 maternal death from hemorrhage. The fetal mortality was 31.97 per cent. Forty one cases were treated expectantly for from 15 hours to 67 days and in this group the fetal mortality was 25.6 per cent. In the entire series 11 more babies might have been saved by expectant treatment.

R. C. THOMAS. In 188 cases treated expectantly the infant mortality was 23 per cent. By delaying examination it was possible to carry 125 infants to at least 38 weeks and another 25 to at least 36 weeks. The mortality associated with scalp traction was

only 12.8 per cent in 47 cases as compared to 57 per cent in 7 breech presentations.

J. HALLWORTH. This speaker emphasized the fact that if the placenta is situated on the posterior wall descent of the presenting part may be delayed because of shortening of the true conjugate, and thus hemorrhage might not be controlled. He advocates cesarean section in such an instance.

PRESIDENT. Rupture of the membranes or cesarean section produces the best results with version, bringing down a foot or scalp reaction the mortality is too high. J. ROBERT WILLSON, M.D.

LABOR AND ITS COMPLICATIONS

Wrigley A. J. The Problem of Postmaturity *Proc. R. Soc. M., Lond.*, 1946 39 569.

The author after reviewing the available literature, both in textbooks and medical journals concerning postmaturity concludes that the diagnosis can be made only with difficulty and that there is no unanimity of opinion concerning the management of patients who go past the expected date of confinement. He states that the height of fundus, the circumference of the abdomen, engagement or non-engagement of the fetal head, and x rays are of little help in establishing the diagnosis. The only way in which postmaturity can be determined is by repeated examination of the patient near term with the following points in mind:

1. Unusual fetal size can usually be determined on repeated examination.

2. As the muscles of the fetus develop they acquire more force and the fetus becomes rigid, this is not characteristic of premature or term infants.

3. Since the quantity of liquor amnii does not increase the enlarging fetus becomes more readily palpable and appears to fill the uterus completely.

When these signs are present the author assumes that the infant is postmature regardless of the duration of amenorrhea and suggests that the pregnancy be terminated by medical induction of labor followed by surgical induction if the former procedure fails.

J. ROBERT WILLSON, M.D.

Brown H. O., Thomson, J. M., and Fitzgerald J. E.: An Analysis of 500 Obstetrical Cases Managed under Continuous Caudal Anesthesia with Pontocaine *Anesthesiology* 1946 7 355

The authors review the recent literature concerning the techniques, results and dangers of caudal anesthesia, and present a detailed analysis of a series of 500 obstetrical cases in which continuous caudal anesthesia with pontocaine as the anesthetic agent had been used. They contend that since only one-tenth as much of the agent is necessary as compared with procaine, the sixfold increase in toxicity of the former drug makes it safer than the latter, the total comparable doses being smaller. In addition to this the use of 1 x 1000 suprarenin as a vasoconstrictor prolongs the anesthetic action, thus further diminishing the total amount of anesthetic agent needed.

INTERNATIONAL ABSTRACTS OF SURGERY

The initial test injection (8 c.c. of 0.10 per cent solution) contained 8 mgm. of the drug. Subsequent injections were 30 to 35 c.c., as necessary. The first dose after the test injection usually relieved pain for from 3 to 5 hours but subsequent doses lasted for shorter periods of time.

Caudal anesthesia is indicated for relief of pain during the latter part of the first stage of labor for delivery of primigravida, to afford rest in prolonged labor to prevent the need for inhalation anesthesia in premature labor in cardiac disease and in eclampsia. The contraindications include inexperience of the operator, local infection, obstetrical complications such as placenta previa, premature separation, cephalopelvic disproportion and contemplated need for uterine relaxation, as for version and extraction. In addition, obesity, deformity, debility, anemia, neurologic disease, hysteria, syphilis, sensitivity to local anesthesia, and pilonidal dimples may be contraindications.

The needle is inserted with the patient in Sims or modified knee-chest position, and is replaced by a catheter after which the test dose is injected. The criteria used to verify accurate placement of the needle or catheter in the caudal canal are as follows: (1) typical sensation on inserting the needle, (2) contact with bone superficial to the midline of the sacrum, (3) the needle parallels the midline of the sacrum, (4) ease of injection, (5) freedom from aspiration of blood or spinal fluid, (6) negative impact test over sacrum when a c.c. of the fluid are forcibly injected, (7) absence of subcutaneous crepitation when air is injected, (8) aching pain with rapid injection, and (9) ability to pass the catheter freely beyond the tip of the needle.

The incidence of operative deliveries was 69.8 per cent as compared to an average of 8.55 per cent of forceps extractions in a total of 6,997 deliveries, occiput transverse or posterior presentation occurred in 19.8 per cent of cases.

Ten babies died however in 9, factors unrelated to anesthesia were thought to be responsible. One baby died from aspiration due to the early onset of respiration. There were no maternal deaths. In 46 (9.2%) of the patients, a fall in blood pressure of more than 20 points was noted and in 18 the fall was greater than 30 points.

The complications were as follows: The dura was penetrated in 5 instances, the needle broke 4 times, 5 superficial skin infections occurred and in only 4 was severe chills following the injection and in only 4 was fever associated with fever. Motor and sensory weakness persisted longer than 24 hours in 4 patients (for 6 months in 1 patient). One patient had fecal and urinary incontinence lasted for 6 weeks.

Satisfactory anesthesia and analgesia were obtained in 428 cases. Failure to insert the needle occurred in 23 cases. In 16, inadequate time or dosage was responsible for the failure, in 16 technical difficulties occurred, and in 6 the needle was removed for other reasons.

Mendelson C. L.: The Aspiration of Stomach Contents into the Lungs during Obstetric Anesthesia. *Am. J. Obst.*, 1946, 52, 19

In a series of 44,016 pregnancies at the New Ten Lying In Hospital, the author observed 66 (0.15%) of aspiration of stomach contents into the lungs during obstetric anesthesia. Gastric reflux of solid and liquid material is prolonged during labor and the aspiration of vomitus into the lungs may occur while the laryngeal reflexes are abolished during general anesthesia. Bronchial configuration favors right-sided respiration, but massive aspiration involves both lungs.

Aspiration of solid material produces the classical picture of laryngeal or bronchial obstruction leading to massive atelectasis with dyspnea, tachycardia, cyanosis, mediastinal shift, and signs of consolidation over the collapsed area. X-rays reveal a homogeneous density in the affected area and varying degrees of mediastinal shift.

Aspiration of liquid contents produces an anesthetic syndrome. There is cyanosis, tachycardia, and dyspnea, but no mediastinal shift of masses and wheezes, rales, and rhonchi are heard over the affected portions of the lungs. Inspiration over the affected densities without mediastinal shift is shown in the roentgenogram. This syndrome is due to the irritation of gastric hydrochloric acid to the bronchial spasm, and a peribronchovascular and congestive reaction. Animal experiments were carried out.

The author believes that the aspiration of stomach contents into the lungs is preventable, and recommends appropriate precautions. Active treatment that of relieving obstruction in the first group, and the use of oxygen, amorphous, adrenalin, and atropine to relieve the bronchospasm in the latter group.

EDWARD L. CORNELL, M.D.

Odell, L. D., and Plasse, E. D.: Intraperitoneal Fever. A Preliminary Study. *Am. J. Obst.*, 1946, 52, 14

Fever during labor may be due to dehydration, extragenital disease, or birth canal infection. The last is diagnosed by excluding the other two, or by the discharge of foul material from the tract. The primary lesion in infections of the genital tract is the amnionitis (placentalitis) which subjects both mother and the child to serious sequelae. In the mother, postpartum infection frequently develops and may be fatal, while aspiration pneumonia and septicemia by direct extension into the placental vessels constitute the chief risks to the child.

In this series of 187 febrile labors, 139 of the mothers presented evidence of birth canal infection. In the latter group 8 mothers and 61 infants died. Mortality rates of 6.2 per cent and 46.9 per cent, respectively. Dehydration fever was followed by maternal or fetal deaths, but pyrexia of extragenital origin (no evidence of uterine infection) led to a maternal death rate of 36.8 per cent and a fetal mortality rate of 42.2 per cent.

J. ROSEMARY WILSON, M.D.

Treatment of dehydration fever and of extragenital diseases followed the usual methods. On the other hand therapy of intrapartum birth canal infections has been significantly and favorably altered by recognition of the dangers involved and by the use of the newer antibiotics, the sulfonamides and penicillin, prophylactically and curatively.

EDWARD L. CORNWELL, M.D.

PUERPERIUM AND ITS COMPLICATIONS

Vara, P: Puerperal Infections and Sensitiveness to Streptococcal Toxins. *Acta obst gyn scand.*, 1946 56 413.

This article deals with an attempt to determine (by means of the Dick skin test) which obstetric patients may be more susceptible to puerperal infections.

The author presents a statistical review of puerperal infections observed in the Women's Division of the Helsinki University during the 20 year period from 1925 to 1944. This review reveals a definite reduction in the incidence of the mild forms of endometritis but none in the incidence of septic endometritis with the hemolytic streptococcus and blood stream invasion.

The results of intracutaneous tests performed on 1,000 women at term were as follows:

Incidence of Reaction to Dick Test Per cent	Incidence of Infection Per cent
+ 6.9	5.88
= 13.6	4.35
- 80.5	1.30

Serious infections were likewise more common in the first two groups. Internal examinations and manipulations raised the incidence of infection in all groups, but to a less degree in the Dick negative

group. The author concludes that the test should be made routine so that the Dick positive and Dick positive/negative group may be handled with greater care and provided with prophylactic chemotherapy.

JAMES F. DOXNELL, M.D.

MISCELLANEOUS

Outgley, J. K.: An Analysis of Maternal Deaths for 12 Years in Monroe County Including Rochester. *N York State J M*, 1946 46 1929.

The analysis of maternal deaths for a 12 year period in Monroe County New York is presented. A total of 232 deaths are recorded among 81,446 births for the period from 1933 to 1944 or a maternal mortality incidence of 2.8 per 1,000 births. Accidents and complications incidental to early pregnancy accounted for 50 deaths which would materially reduce the term or near term incidence. Thirty-two deaths were directly due to infected or septic abortion, 3 to abortion without sepsis and 15 to ectopic pregnancy.

Puerperal septicemia accounted for 15.9 per cent of all the deaths, puerperal hemorrhage for 12 per cent, and toxemias for 12.5 per cent. There were 26 instances of eclamptic death of which 15 were judged to have occurred following adequate prenatal care. However, a more critical breakdown of statistics showed that from 1933 to 1937 there were 16 deaths due to eclampsia among 29,607 deliveries, or 1 in each 1,850 while from 1938 to 1944 there were only 10 deaths among 51,839 deliveries or 1 in each 5,184.

Phlegmasia and embolus with sudden death occurred 26 times, or in 11.2 per cent of the total. There were 40 deaths (17.2%) due to extrapuerperal causes such as heart disease, pneumonia, and various surgical complications. GEORGE BRADLEY, M.D.

GENITOURINARY SURGERY

ADRENAL, KIDNEY AND URETER

Sabadini L.: The Value of Early Pyelography and Functional Tests in Contusions of Kidneys (Valeur de la pyélographie précoce et l'essai des examens fonctionnels au cours des contusions du rein) *J. urol. med. Par.* 1944 1945, 53 305.

The danger of infection by the contrast medium and the aggravation of hemorrhage by traumatism militate against pyelography in renal contusions, according to the prevailing opinion. The author does not share this view because the contrast medium is sterile and even possesses bactericidal properties, and the procedure does not cause any trauma.

He employed early pyelography in 8 patients with intrarenal and 7 patients with extrarenal lesions. The opaque medium was injected in the course of a few hours after the accident, after termination of blood clots. Ureteral catheters were never occluded by blood clots. In spite of the fact that no prophylactic measures had been employed, no infection followed pyelography and the slight elevation of temperature observed in only one patient was attributable to pulmonary complications.

Even repeated procedures did not aggravate the symptoms nor produce any infection or recurrence of hemorrhage.

As to the value of pyelography in renal contusions, the studies may reveal the location of the lesion and involvement, if any, of perirenal tissues. In minor injuries negative x-ray findings strengthen the sense of security, while in more serious injuries absence of evidence of grave lesions in roentgenograms suggests conservative treatment. Finally in very serious injuries the corresponding findings corroborate the clinical diagnosis. Occasionally pyelography may reveal serious lesions not detectable by clinical examination.

Elevation of the left side of the diaphragm and its immobility combined with the presence of dullness in the lower left thoracic region, confirm the diagnosis of perirenal hematoma.

Functional tests of kidneys are also valuable for the evaluation of the condition particularly from the medicolegal viewpoint.

The author emphasizes the relatively small diagnostic value of hematuria even a considerable amount of relatively long duration does not indicate a grave contusion.

The opaque medium should be injected very slowly through ureteral catheters, with the patient in Trendelenburg position. If an intrarenal cavity is disclosed a perirenal hematoma is small or absent and the patient is in good general condition no exploration is indicated.

If the contrast medium enters the renal parenchyma and perirenal tissues, a suture of the kidney is indicated if the contusion is not very extensive and

the general condition of the patient is serious. If a perirenal hematoma is apparently not very extensive, the contusion of the renal parenchyma is slight, the general condition of the patient is marked and the general treatment is satisfactory an expectant treatment is indicated. Repeated x-ray studies are desirable.

JOSEPH K. NAKAT, M.D.

Hinman, F.: Hydronephrosis. The Surgical Treatment. *Surgery* 1946, 20 337

The author presents a comprehensive review of the accepted methods of treating hydronephrosis. He stresses the fact that the first principle in treatment is diagnosis, which includes not only the proof that the condition is present but a demonstration of its degree and complexity. Obstruction to the urinary flow may be unilateral or bilateral and may be located in the upper or lower portion of the urinary tract. The resulting back pressure often may be small or large, and may be accompanied by

Fig. 1 (Hinman, F.) Method of partial pyelotomy after preduroterolysis. a. Oblique area to be excised anteriorly; corresponding oblong area posteriorly (seen through anterior opening) to be excised c. appearance after closure of a, and f. closure of posterior wound, g. postoperative condition to almost normal size with good ureteropelvic anastomosis.

Fig. 2. Longitudinal incision with closure after method of Hencke-Milikausk. Lower diagrams illustrate a. Insertion of tip of curved clamp through an opening in pelvis into the area of constriction b. Incision made upon tip of this clamp as a guide and c. Incision before closure. Upper diagram illustrates how a double incision (a and b) with closure (c and d) will secure additional dilatation, e (Gibson)

secondary effects elsewhere which add to the degree of renal obstruction independently and thus complicate the therapeutic problem.

The aim of treatment is always the preservation of renal tissue with the least risk. Occasionally non-interference is wisest but usually there is a choice between doing one or more of several different procedures.

Two distinct types of hydronephrosis are recognized an insular hydronephrosis, which is an isolated pyelectasis and hydronephrotic atrophy of pure ureteropelvic origin and a hydronephrosis similar pathologically but due to obstruction and accompanied by changes below the ureteropelvic junction.

The point of view that any hydronephrosis not completely functionless should be repaired is condemned. The patient gains little from the repair of a kidney which would not be able to maintain renal function in the event of the loss of the opposite kidney. However if an uninfected hydronephrotic kidney is capable of performing anywhere near one-fourth to one-fifth of total function, and it is believed that after relief of the obstruction the renal parenchyma of the hydronephrotic kidney has reserve potentialities which would permit its renal units to hypertrophy upon stimulation as would happen

Fig. 3. The nephrectomy tube and ureteral splint a. The metal guides of various sizes and shapes (1, 2, and 3) the one which is most suitable being selected b. Nephrostomy tube (angulated suprapubic drain) c. The metal guide inserted retrograde through an opening in the pelvis with the tube (suprapubic drain) tied to its end by heavy silk suture d. tube and splint in place. (The metal guide pulls the tip of the tube to the pelvic opening. The heavy silk tie is cut. The catheter-splint is passed down the tube through a slit in it at a, and is then threaded on down the ureter through the opening of the pelvis which is then closed, as shown here by a interrupted suture.)

when some disaster struck its compensatory mate repair of the hydronephrotic kidney is indicated. In cases of bilateral hydronephrosis repair of the poor side first is the rule because (1) postoperative renal insufficiency and the danger of anuria will be less and (2) an optimal degree of repair of both kidneys will be secured. In the event of a decision to perform bilateral repair the second operation should not be delayed too long.

A classification of plastic repair operations for insular hydronephrosis is presented and each procedure is listed and illustrated. These procedures have been grouped as follows:

1. Pelvioureterolysis with retrograde dilatation division of aberrant vessel partial pelvicotomy or pelvic plication (Fig. 1)

2. Incision of the stenosis (when the obstruction has not been removed by pelvioureterolysis) by simple longitudinal incision (Fig. 2) Y incision

W incision or multiple longitudinal incisions or the ureteral wall down to the mucosa at the site of stenosis without suturing

3. Reimplantation of the ureter into the pelvis (when the insertion is high or when it seems wise to preserve the blood supply of the aberrant vessel) by complete separation of the ureter and reanastomosis or by lateral (side-to-side) ureteropelvic anastomosis without separation.

4. Combination of one or more methods with ureteral splitting and nephrostomy or pyelostomy (Fig. 3) nephropexy and/or denervation.

In the treatment of hydromepelvic junction obstruction below the ureteropelvic junction removal of the cause of obstruction is the first consideration. Secondary changes resulting from obstruction such as vesical diverticulum, ureterovestibular stenosis and valve formation from an elongated tortuous hydroureter may necessitate further procedures which include diverticulectomy, ureteral mesotomy, reimplantation of the ureter into the bladder or complete ureterolysis with partial ureterectomy.

CLARENCE V. HODGES, M.D.

BLADDER, URETHRA, AND PENIS

Franklin, A. P.: Repair of Defects and Fistulas in the Urinary Bladder. *Am. Rev. Surg.* 11: 1046 3: 484.

Gunshot wounds of the anterior bladder wall with destruction of the pubic bones and lower part of the abdominal wall usually run a grave course because of the seepage of urine into the prevesical and perivesical cellular spaces together with the spread of pelvic bone splinters which encourage the spread of pelvic cellulitis, osteomyelitis, and wound sepsis. These wounds are usually caused by mines which explode at close range and by dum-dum bullets which pass through the soft tissues of the bladder and shrink of the bones of a large firm scar and shrinking of the wound ceases when the regenerative capacity is exhausted. A deep chronic fistula is formed in the bladder or a large defect remains in the anterior bladder wall. The mucous membrane of the posterior wall and parts of the bladder fundus protrude from this defect. Aspiration of urine or emptying by means of the retention catheter are ineffective.

Closure of such fistulas or defects of the anterior bladder by mobilization of the tissues of the anterior abdominal wall and bladder usually results in the separation of stitches and recurrence of the fistula. In bladder operations, the principles applied in maxillofacial surgery are of great value. Closure of oral cavity defects is obtained over a growth of mucous membrane. The author excises the scar and frees the anterior and posterior bladder walls from adhesions. The margin of the defect is freshened. The posterior bladder wall is separated from the peritoneum, brought forward and sutured transversely to the inferior edge of the bladder wound. Extensive mobilization of the lateral walls is inadvisable because vascular injuries occur which interfere

with nutrition of the bladder wall. A pedicle, from 3 to 4 cm. wide and from 10 to 15 cm. long, is cut from the lower part of the rectus muscle and is attached to the pubic bone and the fundus of the bladder and fixed with interrupted catgut. The flap is brought down to cover the entire defect of the bladder and extensive destruction of the anterior rectus muscle is present. A flap of the abdominal rectus muscle about 5 cm. long, is excised at the level of the umbilicus together with its aponeurosis by means of a scalpel parallel to the direction of the fibers of the external oblique muscle an aponeurotic pedicle is excised together with the vessels and nerves, is of the same length as the muscular flap, and is attached to the aponeurosis of the external oblique muscle. The flap is directed downward, and contains a muscular flap on a vascular aponeurotic pedicle. The flap is directed downward, and is sutured to the suture line of the urinary bladder, and attached partly to the bladder and partly to the lateral edges of the wound defect of the anterior abdominal wall.

In another cited case, the gracilis muscle was grafted to supply the injured mucous membrane with a muscular lining, a skin tube was cut out with a longitudinal slit 30 cm. long in order to form a Flapov flap and in the lower third of the middle third and part of the lower third of the gracilis muscle was inserted. The skin defect under the Flapov flap was closed by the distal end of the Flapov flap was cut off and a length of 8 cm. of muscle was extracted from its skin sheath, laid on the bladder, and sutured with interrupted catgut. The skin flap was sutured to form a funnel shaped opening and was fixed with interrupted silk suture to the skin of the anterior abdominal wall. The technique of muscle grafting replaces a portion of the bladder wall by striated muscle, which forms a firm lining for the inner surface to be covered by mucous membrane. D. von Rosenstock, M.D.

Cecil, A. B.: Repair of Hypospadias and Diverted Penile. *J. Urol. Med.* 1946, 50: 187.

The author has designed an operation for the repair of hypospadias which is intended to correct a fault inherent in the classic Bucknall procedure. In the Bucknall method, the skin of the scrotum is utilized to form a part of the urethra and cases have been reported in which it was necessary to remove the scrotum which had formed on the basis of the skin. The author recommends formation of the urethra from the skin of the penis.

Division of the urinary stream is secured by perineal urethrotomy. The urethra is formed distal to and including the hypospadias opening by drawing up longitudinal skin flaps to form a tube (Fig. 1). The newly formed urethra is then buried in the scrotum by a midline incision in the scrotum. At a later date, after healing has occurred, the scrotal skin is incised around the penis to leave a wide skin margin. The penis is freed from the scrotum and drawn upward carrying the urethral tube with it.

Fig. 1 (Cecil, A. B.)

the scrotal skin is sutured over the urethra, and the skin defect remaining in the scrotum below is sutured.

The author states that slight variations of this operation make it applicable to the cure of one or any number of urethral fistulas, no matter of what degree.

CLARENCE V. HODGES, M.D.

GENITAL ORGANS

Hansen, T. S.: Fertility in Operatively Treated and Untreated Cryptorchism. *Acta chir scand.* 1946 94 117

The object of this work was to investigate the fertility in operatively treated and untreated cryptorchism on the basis of sperm examinations carried

out according to modern methods. On the basis of the sperm examinations, the presumed impairment of fertility is classified as slight, moderate, and severe; the frequency of abnormal heads, the amount of the ejaculate, and the motility being at the same time taken into consideration. Sterility has only been inferred in cases of aspermia. The material comprises 124 patients in all.

Examination of the sperm from 9 patients with untreated bilateral cryptorchism revealed aspermia in all cases, and thus sterility.

Examination of the sperm from 25 bilaterally cryptorchic men treated with orchidopexy revealed 14 cases of sterility, 4 of presumably severe, 2 of moderate, and 3 of slight impairment. In 2 cases only no sign was found of an impairment of fertility.

These results show that the fertility in bilateral operatively treated cryptorchism is essentially poorer than the literature would seem to show.

Examination of the sperm from 36 patients treated with orchidopexy owing to unilateral cryptorchism, showed 3 cases of sterility, 4 of presumably severe, 4 of moderate and 10 of slight impairment of fertility while 15 exhibited no signs of an impairment of fertility.

Examination of the sperm from 35 patients with untreated unilateral cryptorchism revealed 1 case of sterility, 7 of presumably severe, 3 of moderate and 11 of slight impairment of fertility while 13 exhibited no signs of an impairment of fertility.

A comparison of the two materials of unilaterally cryptorchic men shows that both the separate items of the sperm examination and the fertility estimates are very nearly identical. In addition it is seen that the patients in the author's material produce, on an average, half as many spermatozoa as the men of a large normal American material. This result and the identity between the examinations of treated and untreated cryptorchic men would seem to show—like the examinations of the operated upon bilaterally cryptorchic patients—that no essential production of spermatozoa takes place in the operated testes.

On the basis of these investigations certain lines of treatment are suggested which are deemed advisable in the various forms of cryptorchism. Unilateral cryptorchism requires no treatment with a view to fertility. In bilateral cryptorchism a possible spontaneous descent should be awaited, occasionally in connection with hormonal treatment. Bilateral orchidopexy should not be performed lest it result in bilateral testicular atrophy.

JOHN E. KIRKPATRICK, M.D.

Hultberg, S.: Results of Treatment with Radiotherapy in Carcinoma of the Prostate. *Acta radiol.*, Stockh., 1946, 7: 339.

One hundred and sixty-seven cases of carcinoma of the prostate treated by irradiation at Radium hemmet from 1929 to 1940 are reviewed. Of these, 107 were inoperable and these received radiation therapy alone, 46 cases received postoperative radiation therapy, and 15 of these had been subjected to a previous radical operation. In 14 patients with local recurrences or metastases after a previous operation, radiation therapy was given. The author believes that the perineal approach gives a better exposure and the opportunity to diagnose prostatic carcinoma at an earlier stage. By this route a more radical removal of the lesion and a better ultimate result is attained.

Of the inoperable patients, 16 per cent survived for more than 3 years, and 54 per cent for more than 5 years. Of the patients who were operated upon, 38 per cent survived more than 3 years and 30 per cent more than 5 years.

Seventy patients received only x-ray therapy, 25 teloradium and 65 a combination of both. Of those treated with x-ray alone, 13 per cent lived for more

than 3 years and 14 per cent for more than 5 years. Among the cases which were treated with teloradium alone or in combination with x-ray, 24 per cent survived for more than 3 years, and 12 per cent for more than 5 years.

Those patients who had metastases at admission or who subsequently developed them had a mean period of survival of 12.0 months from the time when the metastases were first demonstrated.

FREDERICK A. LUND, M.D.

Vest, S. A., and Frazer, T. H.: Survival following Castration for Prostatic Cancer. *J. Urol.*, L., 1946, 56: 97.

Vest and Frazer state that from a study of the literature reasonably correct evaluations of several of the itemized topics are evident, while in other instances data are presented which give diametrically opposed impressions.

- 1 Symptomatic improvements (a) relief from pain for varying periods of time (b) relief of symptoms of urinary tract obstruction to a varying degree (bleeding, residual urine, improvement of infection) (c) improvement of general well being (strength, vigor, appetite, weight, anemia)
- 2 Value of hormone control therapy in producing regression of the local and metastatic growth of prostatic cancer
- 3 Value of serum acid and alkaline phosphatase in diagnosis and prognosis
- 4 Histological changes in the cancerous area following hormone control therapy
- 5 Therapeutic effects relative to grade or differentiation of the cancer
- 6 Changes in the hormone excretion pattern of the urine from both quantitative and qualitative standpoints
- 7 Response to orchiectomy in patients of different age groups
- 8 Results of treatment when compared to the duration of disease before the treatment was instituted
- 9 Evaluation of orchiectomy as prophylaxis against local growth, extension of the tumor and metastases
- 10 Consideration of the results in so-called prophylactic cases or those with early metastatic cancer as compared with those in cases with metastases
- 11 Value of castration versus estrogenic therapy
- 12 Value of the various estrogenic substances alone, before, with, or after castration
- 13 Effect of various estrogenic substances on tissues other than the prostatic cancer
- 14 Effect of x-ray therapy directly to the adenoma and pituitary gland in combination with other hormonal control methods
- 15 Life expectancy or survival after hormone control therapy as compared with that following the many other therapeutic procedures that have been used to combat this disease

In a study of the literature it is evident that much more time must pass before many of the numerous questions concerning effects following hormone control therapy can be answered. One of the most important questions concerning orchiectomy for prostatic cancer is the possible effect on survival time following treatment. The survival time in the last analysis is certainly the best statistical measure of any therapeutic procedure. There exists a complete lack of uniformity in presenting statistics pertinent to survival rates following hormone control therapy. Many others fail to report closed series of cases and following closure at least 2 years must elapse before any report of value can be made.

Another extremely important question following orchiectomy or estrogenic therapy is whether or not treatment should be instituted early in the course of the disease before metastases have occurred, or whether treatment should be withheld until late in the disease when the symptoms, extension and metastases are severe. A number of years will be necessary as well as a larger number of cases before definite evidence can be obtained as to the survival of life in patients following orchiectomy for prostatic cancer. The final basis for any conclusions or deductions must necessarily be based upon comparison with results in cases treated by methods before the use of hormone control therapy.

The authors report their series of 74 closed cases (series closed December 31, 1943) and try to compare these with the 5 other reports in the literature. They suggest that authors in the future report the number of patients that died in successive 6 month intervals. There is no reported series of cases before the advent of hormone control therapy that is comparable to the series reported at present with the result that a reasonable evaluation of this modern hormone control treatment cannot be made. More studies of survival time are stressed and authors are urged to report cases so that comparative studies and conclusions can be made. DAVID ROSENTHAL, M.D.

Hesbit R. M. and Lynn J. M. Malignant Testicular Neoplasms. *Surgery* 1946 20 273.

This study is based on 80 cases of malignant disease of the testicle which have been followed up for 4 years or longer.

The youngest patient was 3 years of age, the oldest 66 and the average age for all the patients was 35.7 years. The average duration of symptoms before diagnosis was 30.5 months, the shortest duration of tumor was 1 week, and the longest 15 years. Neoplasia in an undescended testicle occurred 4 times. Attention should be called particularly to the 3 patients in this group whose presenting clinical picture and history closely resembled acute epididymitis.

Malignancies of the testes are known to metastasize early although no dissemination could be clinically demonstrated in 51 of the group of patients when they first came under observation.

The ideas of various writers with regard to hormone assays on the urine have differed rather widely

In the past. Ferguson once believed that the type of tumor that would be diagnosed microscopically and the presence of metastases could be rather accurately predicted in many cases from the prolan level. More recent work however by Dean Hinman and others indicates that a negative response to a test for prolan means nothing but that a positive response dictates a grave prognosis. The titer of prolan A should be at least 500 mouse units or luteinizing hormone should be present before the test is considered significant since low levels may be due to the follicle stimulating hormone present in the urine of castrates.

The question arose as to whether a tumor which gave rise to a negative Aschheim Zondek test before therapy would ever cause a positive reaction after treatment. Since metastases from teratoma testis are often more malignant microscopically than the primary focus from which they originated one would postulate an affirmative answer to this query.

If the Aschheim Zondek test is positive the outlook for survival is grave. Of 8 patients having hormone levels above 500 mouse units before treatment, only 2 are living. One of these patients had chorioepithelioma and there was no recurrence 12 years after operation. (The case is being reported completely elsewhere.) All 8 patients with positive determinations after therapy are dead.

Nineteen patients were treated by simple orchiectomy, and 5 (26.3 per cent) are alive after an average period of 9.3 years. The authors definitely agree that persons with testicular malignancies other than chorioepithelioma should have postoperative x-ray therapy to the pelvis and abdomen whether or not metastases can be demonstrated.

The assertion has been made that if neoplastic disease of the testicle could be diagnosed early enough a great many more of the patients could be saved through the benefit of early operation. Accordingly the 51 patients without demonstrable metastases were divided into two groups: those who were treated within 2 months of onset of symptoms and those treated more than 2 months after the onset of symptoms. Six of 10 treated "early" and 13 of 41 treated late are living. Application of the chi square formula to these figures reveals no significant difference and although one might assume that early treatment would yield better results, the authors were unable to prove that such is the case.

The use of preoperative irradiation for the testicle which is the site of a neoplastic process has been a point of considerable controversy, and a conclusive answer to the question can probably not yet be given. Arguments against preoperative x-ray treatment are as follows: (1) the leaving *in situ* of a very malignant neoplasm which is known to metastasize early and (2) the possibility of incorrect diagnosis because x-ray therapy sometimes renders subsequent microscopic interpretation difficult or impossible.

In the literature one finds frequent mention of radical retroperitoneal lymph gland dissection for testicular cancer—the Chevassu Hinman operation.

It has been demonstrated that in 90 per cent of bodies there is a communication of the retroperitoneal lymph chain with glands above the renal pedicle and into the chest and for this reason most surgeons have abandoned this procedure.

In studying the series of cases one conclusive fact has been brought to light that a metastatic neoplasm which fails to regress or which becomes clinically evident following initial irradiation will not respond favorably to additional deep therapy. The average survival of patients was 12 months.

For the clinician chaos is the only word which adequately describes the present conflict of opinion regarding the pathology of testicular neoplasms. For this reason no attempt has been made to correlate survival method of treatment, and the pathologist's opinion of tumor tissue examined microscopically. The chief difference has been that some hold to the theory that all testicular tumors are teratoid in origin (advocated by Ewing and followers), while others maintain that the seminoma is a distinct entity not arising from totipotent cells (Chevassu and disciples).

Korhonen, A.: Nonspecific Acute Epididymitis (Serles epididymitis alguta non specijica). *Acta chir scand* 1946, 93 270

During wars infectious diseases which in normal times occur only sporadically are often observed in almost epidemic proportions. One of these is non-specific acute epididymitis.

The author discusses a series of 40 cases observed in the Finnish army during active service in the last war. The disease starts with low grade fever of about 1 week's duration and pains and swelling in

the caudal part of the epididymis, it is painful, always unilateral. Although the fever never exceeds 8 days, the swelling subsides very gradually, its restitution ad integrum taking place usually in from 4 to 6 weeks. The swelling may increase up to the size of a hen's egg but almost always it involves the caudal part only. In rare cases, secondary involvement of the superior part and of the ductus deferens occurs. As to the laboratory findings, the most significant one is a rise of the sedimentation rate to between 20 and 30 (Westergren) which is observed in all cases. In no case was there any discharge from the urethra, nor was any pathogenic change in the prostate gland ever observed. The urine was normal in all cases except for a few white cells. Bacteria were never found in the urine.

The treatment included bed rest, cold applications, and small doses of sulfathiazole during the first week. The prognosis is good, and recurrences are very rare.

As to the etiology the author rejects the theory that the disease is caused by staphylococci of low virulence; he believes that the epididymitis is a hematogenous infection caused by an unknown virus. It seems to be highly contagious under poor hygienic conditions although the way of transmission is unknown. In overcrowded places as in underground shelters, contact infection seems to play the most important role.

Treatment should always be strictly conservative. Surgery is definitely contraindicated unless the disease becomes chronic, but this did not occur in any of the author's cases. In its course and epidemiology the disease shows great similarity to infectious hepatitis.

WALTER M. SWEENEY, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS

CONDITIONS OF THE BONES, JOINTS, MUSCLES TENDONS, ETC.

Mathew, J. A.: The Problem of Osteochondritis Dissecans. The Cause of the Constant Convexity of the Base of Its Niche and the Explanation of Its Frequent Occurrence in Cretinism (Le problème de l'ostéochondrite disséquante la raison de la convexité constante du fond de sa niche explication de sa fréquence relative dans le crétinisme) *Presse méd.*, 1946 54 311

Dequervain and his associates observed that osteochondritis dissecans very frequently occurred in cretins. Based on the experiments of a number of authors it is well established that osteochondritis dissecans is caused by a force of vibration. A vibrating force of moderate intensity exerted on the femoral condyle forms a zone of Looser. A more intense force causes a discrete separation of the osseous tissue.

Osteochondritis dissecans is always found at the apex of the curved femoral condyle and opposite one or the other of the tibial spines. It occurs most frequently opposite the medial tibial spine. If one compares a femoral condyle with a ball one readily understands what takes place in a knee afflicted with osteochondritis dissecans. A force exerted on the femoral condyle (or a ball) will show the greatest amount of compression in the center of the impact. The slope of the compression levels off radially from the center of the impact. This theory also holds true in cases of osteochondritis of the elbow joint and of the hip joint.

There are cases of osteochondritis dissecans which are not associated with any pain. As long as the pathological changes are confined to the "Zone of Looser" the condition usually remains asymptomatic. When the osseous structures are fissured pain usually is present. Barth believes that the posterior cruciate ligaments are responsible for the occurrence of osteochondritis dissecans. The author raises the question as to how the posterior cruciate ligament can be made responsible for the constant convexity of the base of the niche.

Osteochondritis dissecans most frequently occurs in the knee joint. The menisci are the stabilizers and shock absorbers of the knee joint. Therefore, it is clear that a torn medial meniscus will diminish the resistance of the femoral condyle to the force of vibration. Bircher reported in 1929 the frequent occurrence of torn meniscus and osteochondritis dissecans in the same knee joint. Henschen has demonstrated that the soft tissues of the body are liable to be fractured by vibration just as well as by the firm bony structures. Fromme reported in 1921 that the "zone of Looser" responds very satisfactorily to rest and it was his belief that prolonged complete rest could lead to disappearance of the osteochondritic lesions.

The occasional occurrence of bilateral symmetrical osteochondritis dissecans lesions make it impossible to accept Arlitz's theory of vascular impairment or the theory of Barth that osteochondritis dissecans is caused by the posterior cruciate ligaments. It is the author's opinion that in these cases the congenitally sharply pointed curvatures of the femoral condyles favors the occurrence of symmetrical osteochondritic lesions in both knee joints.

The histological findings also favor the author's point of view. The picture is that of necrosis rather than that of inflammation.

In the surgical clinic at Zurich Howald has shown that in cases in which the x rays show bony fragments within the osteochondritic lesions he was never able to find loose intra-articular bodies. At operation he found that the articular cartilage covered the lesion and that it was therefore hard to find. The fragments visible on x-ray examination represent necrotic bony fragments which often become completely absorbed. Howald states that when this occurs loose bodies appear within the joint cavity. Soon after the bony fragments become absorbed the overlying articular cartilage detaches and lies freely in the joint cavity.

All this can be explained along the lines of the author's theory of the pathology of osteochondritis dissecans. A trauma will loosen the less flexible bony structures sooner than the elastic cartilage. The loosened bony fragments are deprived of their source of nourishment and will readily undergo necrosis. The articular cartilage however will continue to get its nourishment by osmosis from the synovial fluid.

The fact that osteochondritis dissecans occurs in cretins with thyroid and parathyroid disturbances can be explained by the fact that because of these disturbances the bony structures become weakened. The coxitis varus, so frequently observed in cretins, is due to a deformity of the distal humeral epiphysis. This deformity is caused by the fact that the child walks on its hands and knees and that the weakened bony structures of cretins become deformed. The same reason holds true in the formation of coxa vara in cretins. Feistman examined 34 hip joints of cretins and found 32 of them deformed. Bircher has found that the ossification of the long bones is disturbed in cretins. There is an irregular number of ossification centers in the long bones of cretins. Wegelin reports that the normally found areas of softening and degeneration of the articular cartilage were greatly increased in cretins.

The weakness of the cartilage of grown cretins is illustrated by the defects found in the cartilage which have occurred after the ossification of the epiphyses had been accomplished.

In conclusion the author points out that the constant occurrence of a convexity at the base of the

GEORGE L. RENK, M.D.

Epiphyseolysis of the hip indicates a slipping of the head of the femur. Based on the gross pathology and therapeutic possibilities there are four stages: (1) the incipient stage, (2) the stage of moderate slipping, (3) of severe slipping and (4) of acute slipping. The last two stages are usually very painful. The first two stages are usually very

On physical examination the patient appears to walk with a slight limp and keeps his affected leg in outward rotation. The extension and outward rotation of the hip joint usually is normal. Often a slight flexion of the hip joint is observed. Inward rotation is very definitely and always restricted.

Once the diagnosis of incipient epiphyseolysis of the femoral head has been made the treatment should be instituted immediately. It is the author's contention that if the epiphyseal plate is made to fuse, further complications such as traumatic arthritis can be averted. There are several methods in use to accomplish fusion of the epiphyseal plate. The author, however, uses drilling as a means of fusing to the neck.

The postoperative care consists of the application of a plaster hip spica which is left on for 3 months. During this time the patient stays in bed. He re-

turns to the hospital at the end of this period which time a roentgenogram is taken. The epiphyseal plate is, as a rule, found to be thicker than the physal plate is. Another plaster of Paris shows partial absorption. Another plaster of Paris is applied and left on for an additional six months. The hip spica extends to the middle of the leg and walking with crutches is allowed. Three months later another roentgenogram is taken. At this time the epiphyseal plate usually is very thin and the juxtaepiphyseal sclerosis has disappeared. The patient is given a Thomas leg brace with a ischial seat bearing. This brace is worn for an additional 6 months or longer until the roentgenogram shows complete fusion of the femoral head and neck. By the use of physical therapy the latter period of treatment is kept mobilized during the latter period of treatment. In conclusion the author presents 4 cases with the corresponding roentgenograms and mentions the fact that he has treated 13 additional cases in the same manner with very satisfactory end-results.

GEORGE I. RICE, M.D.

Brachetto-Brian D : The Origin and Evolutionary
Cycle of Giant Cells of Tumors of the Bone.
Benign Variant Preliminary Communication
(Origin y ciclo evolutivo de la microploidia de los
tumores de los huesos, var. benigna. Comunicación
previa) Arch. Soc. argent. anat. 1944, 6 : 55

While studying a hemorrhagic zone in a giant tumor from the upper epiphysis of the humerus, the author discovered a certain syncytial cell having a large nucleus, one or two nucleoli, basophilic reticulum, and a basophilic cytoplasm. Mitoses were observed, and also an amitosis prior to the division of the nucleus and formation of daughter cells. The latter were termed juvenile myeloplasm or myeloplaxoid because the nucleus was much the same as the nucleus of the syncytium.

The evolutionary cycle of these cells was stated under the headings of (1) origin and growth; (2) the under the headings of (3) old age, and (4) death. In the adult form (3) old age, and (4) death. In the first (myeloplaxidite I) the cells contained from 1 to 10 nuclei. Direct division of the cytoplasm. In the second class (myeloplaxidite II) augmentation of the basophilic cytoplasm prior to fission and plasmocytosis were seen. In these cells the nuclei were 100 in the old age class (myeloplaxidite III) the nuclear volume decreased the ovoid shape of the nucleus changed to an irregular polyhedron, the basochromatin became condensed, nucleoli were no longer visible, and pyknosis was present.

The architecture becomes clarified if the evolution of blastomas as outlined is accepted. The intervention of the giant cells in the softening of the fundamental substance of blastomas is understandable the contribution that occurs and the contribution to the breaking-down phenomenon and epiphyseal destruction have a basis in fact in the light of this article.

STEPHEN A. ZIMAN, M.D.

Marique, P: Polycystic Xanthoma of the Meniscus (Xanthome méniscal polykystique) *Acta orthop Belg* 1946 12 121

Pathological conditions of the meniscus of the knee are chiefly traumatic ruptures. Congenital malformations and cysts are less frequent and tumors are rare.

The author describes a case of polycystic xanthoma of the external meniscus of the left knee in a woman of 35. Cysts are twice as frequent in males as in females. She had suffered a blow on the left knee some years before and the tumor had developed gradually accompanied by pain. Examination showed a tumor the size of a filbert in the middle of the external interline. It was quite hard and protruded much more on extension than on flexion. It did not interfere greatly with movement. There was considerable atrophy of the muscles of the thigh.

Operation was performed under spinal anesthesia and the meniscus was extirpated completely. The wound healed by first intention. A plaster cast was applied and kept on for 15 days. When it was removed the joint was rigid but flexion to 90 degrees was recovered in 2 months and complete flexion of the heel against the thigh in 3 more months.

Illustrations are given showing the gross and microscopic appearance of the specimen. The solid tumor which was the size of a cherry was in the central part of the specimen and was surrounded by a large cyst and a number of smaller ones. The abundant fatty matter in the tumor was shown to be made up of cholesterol esters. The xanthomatous nature of the tumor was further demonstrated by a positive Liebermann reaction.

Polycystic tumors affect the external meniscus in 80 to 85 per cent of the cases. They are generally multilocular with a mucous content. Several cases of xanthomatous deposits associated with such cysts have been described. They generally show a rich hemosiderin content, many polynuclear giant cells, xanthomatous cells, and lobulation. The described case differed from this typical picture in not showing giant cells or hemosiderin pigment. Henschen explains these xanthomatous deposits as being due to an arthrotropic cholesterinophilia.

AUDREY G MORGAN M.D.

Lerner, H. H., and Gazin, A. I. Interarticular Isthmus Hiatus (Spondylolytic) *Radiology* 1946, 46 573

The authors believe that interarticular isthmus hiatus is probably the result of a hyperflexion injury or fracture through the cartilaginous isthmus sustained either at birth or shortly thereafter. The literature, embryology, and anatomy are carefully reviewed.

In 1853 Killian first described the entity, spondylolisthesis, of Greek derivation meaning slipping of a vertebra. Neugebauer (1892) is to be given credit for the widespread recognition of this condition. Much has been written on this subject by Willis, Mall, Batta, Hitchcock, Chandler, Meyerding, Kleinberg, and others.

Fig. 1 (Lerner, H. H., and Gazin, A. I.) Lateral view isthmus hiatus of third lumbar vertebra.

The diagnosis of interarticular hiatus with or without slipping is based upon the roentgen findings of which there are 5:

1. Demonstration of the hiatus
2. Underdevelopment of the vertebral body
3. Displacement of the vertebra in relation to the adjacent segments
4. Increased total anteroposterior diameter of the vertebra
5. Buttress formation at the anterior lip of the sacrum when the fifth lumbar vertebra slips.

DANIEL H. LEVITHAL, M.D.

SURGERY OF THE BONES, JOINTS, MUSCLES, TENDONS ETC.

Greeley, P. W.: Reconstruction of the Thumb *Ann. Surg.* 1946 124 60.

Thirteen cases of reconstruction of the thumb provide the material for this article. The operation for deepening the web between the existing thumb stump and the adjacent metacarpal was done on 3 patients.

Poicization of a remaining partial finger was not done in this series nor was transplantation of a toe considered desirable.

Ten cases were treated by lengthening the existing thumb stump. The procedure consists in constructing first a tubed pedicle flap of skin and fat from a hairless area on the flank (Fig. 1). This is attached to the thumb stump when circulation from the abdominal end is known to be adequate. Later, when the circulation from the thumb attachment is known to be adequate the abdominal attachment is severed and the tube splinted to prevent strangulation. This new thumb is allowed to become well softened in its new position and then it is made rigid by inserting a perforated bone graft, obtained from the twelfth rib

Fig 1 (Greeley) a, Explains the operative technique for removing the fifth rib. In this case the bone graft was placed first into the tubed pedicle while it was still attached to the abdomen at each end. b, Later the distal end

of the tube was attached to the thumb stump and at the same time the base of the bone graft was sutured into the metacarpal. This order of procedure has been stable because of the difficulty in holding the hand in position without accidentally pulling the bone graft out of the new bed. c and d, Illustration of the case described. See the roentgenogram of the bone graft 16 months after transplantation. Good bony union is noted. (This patient had suffered a greenstick fracture at the base 3 months before the injury occurred during basketball play.) The patient plans to return to a civil occupation as a maintenance instructor in University. The authors feel confident that the restoration will enable him to hold a piece of chalk. (Courtesy of J. B. Lipplacott Co.)

into the core of the tube and fixing its proximal end into a hole drilled into the medullary cavity of the remaining portion of the first metacarpal bone. About 6 months is required for complete bone healing and splinting is continued during this period.

A troublesome complication, noted 8 times was gangrene of the tip of the tube, which appeared from 10 to 18 days after the abdominal attachment was severed. It required excision of the resulting ulcer.

In 3 cases infection and necrosis of the bone graft occurred. The graft had to be removed and later replaced from the remaining twelfth rib. Accidental fracture occurred in 1 patient who played water basketball before healing was complete. The graft healed in approximately 2 months.

The photographs which illustrate this article show that a thumb, satisfactory from both the cosmetic and functional viewpoints can be produced by this method, but phalangeal joint activity is not provided. There is sufficient range of motion at the metacarpal joint to allow for good opposition against the remaining fingers. NEWTON C. MEAD, M.D.

Kallio, K. E.: Plastic Operations on the Thumb (Sur les opérations plastiques du pouce) *Acta chirurgica*, 1946 93 231

In spite of the disability and inconvenience caused by the absence of a thumb a review of the literature does not impress one that much attention has been given to plastic procedures for surgical correction. Most surgeons have an experience covering only 1 or at most 2 or 3 cases. The author presents a series of 10 cases which he divides into two groups, according to whether the material for plastic replacement was taken from the immediate adjacent tissues of the hand or transplanted from other parts of the body.

Huguler in 1853 was the first to practice phalangization of the first metacarpal. This operation involves an incision of the skin fold of the thumb extending dorsally along the arched skin fold at the thenar base thus forming a cutaneous dorsal and volar flap. The first interosseous muscle and the transverse head of the adductor muscle of the thumb are removed. The dorsal cutaneous flap is sutured into the base of the palm and the volar flap to the dorsum of the hand. In 1938 Koester reported 3 cases operated upon by this method and collected 45 similar cases from the literature. The results were unsuccessful in only 2 of the 38 cases in which results were stated. In his opinion this operation constitutes the easiest and most rapid method of producing a thumb with sensibility mobility and power. If one or two other digits besides the thumb were missing, Perthes found phalangization could be rendered more satisfactory by removal of the second metacarpal, or if only the metacarpals remained, as much of the second and third metacarpals as necessary were removed to provide a broader cleft. Schossener however removes only the second in either event. Lukscha, in 1903 described an operation in which a finger of the same hand was transplanted to take the place of the thumb. Buzello transplanted the index

finger and a portion of the second metacarpal. Iselin also reported successful results by this method in 3 cases. Meyer proceeded in this manner to replace a missing thumb by the midfinger. The disadvantage of these methods is that the hand already disfigured, has to be further damaged with sacrifice of otherwise normal digits and the creation of further cicatrices. In a case in which the thumb and index finger were absent, and the remaining fingers had been amputated, Spitzky and Jenner removed the proximal portion of the second metacarpal transplanting it as an elongation of the distal end of the second metacarpal. In the present series 3 cases were treated by simple phalangization. In the first of these in which only the little finger remained intact with very little of the first phalanges of the thumb and index finger phalangization seemed definitely indicated. In the other case in which only the thumb was defective and the rest of the hand normal the first interosseous muscle and the greater portion of the adductor muscle were likewise removed. The new thumb presented good power of adduction. With this incision it was possible to close the defect without undue tension on the skin. A strong sensitive thumb was obtained in both cases with perfect mobility even though in one the thumb was rather short due to the length of the metacarpal. In 2 cases, the author performed a phalangization of the first metacarpal removing the second metacarpal according to Perthes with excellent results.

Nicoladini's first method of correcting defects of the thumb by transplantation of grafts from other body parts consisted of the formation in one or two stages of a tubular skin flap containing bone producing a thumb by uniting it with the first metacarpal. His own attempts did not yield successful results but later writers obtained good results with flaps taken from the abdomen or chest and bone from the tibia, fibula, rib, clavicle, metacarpus or iliac crest. This method was used in 5 cases in the present series. The transplanted bone in the skin tube was absorbed in 4 cases, necessitating repeated bone transplantation and loss of time. The thumbs thus produced were most satisfactory as regards sensibility mobility and strength. All of these thumbs were sensitive to touch and pin prick except at the ends, and four were even sensitive to heat.

In 1 case in which the thumb and first metacarpal were missing excellent results were obtained by a distant plastic performed in three stages. In the second stage a free bone graft was inserted directly into the multangulum majus and after fixation it was introduced into a skin tube formed from abdominal skin at the first stage and simultaneously this tube was then sutured to the hand. This method replaces Nicoladini's first method which should be abandoned.

It is suggested that in estimating disability for compensation claims, this should be judged as between 10 and 15 per cent higher when the first metacarpal is missing. Plastic operations are capable of reducing this disability from 5 to 10 per cent.

EDITH SCHAMBER MOORE

Haggart, G. E., and Hare, H. F.: Combined Roentgen Radiation and Surgical Treatment of Large Benign Giant Cell Tumors of Bone. *Ann. Surg.*, 1946 124, 218.

The authors present the therapeutic technique and results obtained in the management of 7 patients with proved benign giant cell tumor of bone which presented difficult problems in treatment. The treatment consisted of roentgen radiation which was followed by surgical removal of the tumor with thorough curettage and filling of the defect with bone grafts. Neither chemical nor thermal cauterization was employed.

For those benign giant cell tumors of the bone which are readily accessible and can be removed without sacrifice of function, immediate and complete excision is recommended. Examples of such tumors are those observed in the vertebral spinous and transverse process. The preoperative radiation given is described. Postoperative radiation was not given, except to 1 patient who had a 2 stage operation because of his extremely poor physical condition.

The operative process is described and the report of the 7 cases is given in detail with a summary of the results. In each instance the extremity was saved and there has been no evidence of recurrence of the tumor. The affected extremity is now a useful member. The roentgen radiation therapy did not interfere with the reparative process of the tissues following surgery. *ERIC C. ROSENTHAL, M.D.*

Altman H., and Trott, R. H.: Muscle Transplantation for Paralysis of the Radial Nerve. *J. Bone Surg.* 1946 28 442.

Among war injuries many compound fractures of the lower two-thirds of the humerus present an associated paralysis of the radial nerve. In cases of irreparable damage to the nerve, tendon transfer at the wrist has resulted in functional recovery of the hand and wrist in 1 or 3 months. The authors present 18 cases in which permanent radial or dorsal interosseous nerve lesions indicated tendon transplantation.

The technique of Billington with the right angle incision on the extensor surface of the lower forearm employed in the early cases resulted in edema of the hand and elbow in the angle of the incision. Modification of the approach reduced the trauma incident to the handling of the tendons and enabled patients to become ambulatory in 48 hours.

In a few cases this procedure was carried out in addition to nerve repair. This makes the hand useful in a few weeks and most efficiently supports the wrist during the period of nerve recovery.

The surgical technique is presented in detail, transverse incisions proximal to the dorsal carpal ligament are used for isolating the tendons. The pronator teres tendon is threaded through and sutured to the tendons of both radial extensors of the wrist. The tendon of the ulnar flexor of the wrist is similarly attached to the extensors of the index, middle, ring, and little fingers by the buttonhole tech-

nique of Mayer. The radial flexor of the wrist likewise passed through and sutured to both extensors and the long abductor of the thumb.

The tension with which the tendons are implanted approximates the physiological as far as possible. A plaster splint is applied to maintain the fingers in extension and the hand in 30 degrees of dorsiflexion.

The pronator teres transplant is not used if the lesion involves the dorsal interosseous nerve. The arm is elevated from 1 to 3 days after operation when the patient is allowed up with the arm resting if the edema is gone. Fingertip motion in the splint, is begun at once, and after the sutures are removed at the beginning of the fourth week, full active use of the transplants is begun. The splint is worn only at night during the fifth week, and discarded at the sixth week.

Good results were obtained in all cases, each patient leaving the hospital with a functioning hand that had a strong grip. Complete extension and abduction of the thumb were secured in all cases, complete extension at all interphalangeal joints, extension to within 15 degrees of normal at the metacarpophalangeal joints of the other digits. Dorsiflexion at the wrist was possible to 25 degrees beyond neutral. *FRANCIS E. BRIDGES, M.D.*

FRACTURES AND DISLOCATIONS

Colzola, F.: Fractures of the Upper End of the Radius (Fracturas de la extremidad superior radio). *Rev. Soc. de Quir.* 1945, 11: 505.

This form of fracture is more common than is usually believed. Among 5,319 cases of trauma examined by the author from 1912 to 1945, 1,051 were fractures of the upper extremity and of these 137 were fractures of the upper end of the radius. There were 137 fractures of the upper end of the radius constituting 3.6 per cent of all fractures of the arm. Of a total of 176 fractures of the elbow 40 (22%) were of the upper end of the radius, while 43 (24%) were of the supracondylar region of the humerus.

In fracture of the upper end of the radius the external condyle of the humerus is frequently injured also even if it is not fractured there are evolutions of the cartilage which may later cause rigidity of the joint. All contused tissue should be removed by operation. The roentgenogram does not always show the extent of injury in these fractures.

Among the author's cases, 26 (65%) were complete fractures, 4 (10%) partial fractures, and 7 (25%) complete fractures. In the incomplete fractures the author immobilizes the part with a plaster cast for 2 or 3 weeks, followed by active mobilization and Bier's local hyperemia. He had good results in 88.8 per cent of these cases. In recent partial complete fractures he simply extirpates the bony fragment two-thirds of the circumference of the head is removed. In total complete fractures he extirpates the whole head. He had satisfactory results in 87.5 per cent of the surgical cases.

A table of the 40 cases is given showing the name, age and sex of the patient, and the date and mechanism of the fracture. (In 44.4% of his cases the violence was direct while in 55.5% it was indirect. Most authors report a great majority of cases caused by indirect violence—a fall on the hand with the elbow generally extended but sometimes flexed.) The table also shows the variety of the fracture, the treatment, and the early and late results.

AUDREY G. MORGAN, M.D.

Nohrman, B. A.: Fractures of the Elbow with Particular Regard to the Distal End of the Humerus. *Acta radiol.* Stockh., 1946 27 409

A series of 324 persons with 328 fractures of the elbow were observed during the years from 1932 to 1941 and the follow-up examinations were carried out in 1943 and 1944. Sixty-one per cent of the fractures involved the distal end of the humerus. Forty-one per cent of the fractures were in adults and 59 per cent in children. Supracondylar fractures as well as fractures of the humerus are most common in children. Fifty-six per cent of the total were in males and 44 per cent in females. Forty-one per cent of the injuries involved the right arm and 59 per cent the left. Among the supracondylar fractures 78 were of the extension type and 13 of the flexion variety. In those cases in which the reduction was satisfactory a very good result occurred.

The condyle and epicondyle fractures represented about one third of the total material. Fractures of the epicondyle comprised about 50 per cent of the lateral condyle 40 per cent and of the medial condyle 10 per cent. Among 20 cases of epicondylar fracture reduced without surgical intervention the position was not perfect and the bone healed in only 4 of these. Myositis ossificans was seen in 6 fractures of this group.

RICHARD J. BENNETT, JR., M.D.

Pieri, G.: Management of Habitual Dislocation of the Shoulder (*Sulla cura della lussazione abituale della spalla*). *Chir. org. movim.* 1943 29 134.

Existing methods of dealing with the problem of habitual dislocation of the shoulder are directed toward (1) the articulation, (2) the muscles and tendons, or (3) the skeleton. The author describes a method which consists essentially of suspension of the humeral head by means of a slip of the deltoid muscle which is passed through a tunnel from the front to the back and subsequently through an opening in the spine of the scapula. The muscle slip is then secured to the superior surface of the spine.

This method was used in 7 cases, 6 of which presented satisfactory results. One case only showed limitation in power of abduction, which was probably attributable to an extended period of post-operative immobilization.

EDITH B. FARNSWORTH, M.D.

SURGERY OF THE BLOOD AND LYMPH SYSTEMS

BLOOD VESSELS

Warren, R.: War Wounds of Arteries. Arch. Surg. 1916 53 86.

The author presents a survey of 115 patients with arterial wounds, admitted to a general hospital from a few hours to 3 weeks after being wounded. The distribution of these injuries is as follows: carotid artery 11, subclavian artery 1, axillary and brachial arteries, 51, femoral artery 18, profunda femoris, 1, and popliteal artery 30.

The author's experience confirms the teaching that the injury to the internal carotid artery is more serious than that to the common carotid artery, so far as the resultant damage to cerebral tissue is concerned. The syndrome with hemiplegia, no hemiparesis, and the fracture of the mandible, injury to the vagus nerve or its branches, injury to the cervical portion of the sympathetic system, clear spinal fluid, and normal roentgenograms of the cranium, suggest injury to the internal carotid artery. An injury to the common carotid artery is perhaps distinguished from this by the common occurrence of pulsating hematomata, and by the comparative rarity of mandibular fractures and hemiplegia. The most striking features of these patients are neurological signs of hemiplegia and aphasia. It is believed that the explanation of the findings in injuries of the internal carotid artery are on the basis of contusion and arterial spasm since all 4 patients in this group presented small penetrating or perforating wounds of the neck and little or no hematoma. In only 1 patient was there an indication of hemorrhage from this was due to severe secondary hemorrhage from the base of the tongue. A segment of internal carotid artery 1 cm. in length and about 1 cm. distal to its origin, was found to be constricted to about 60 per cent of the normal caliber. The artery was thus transmitting less blood than usual and the consequent transmuting less blood than usual and the consequent condition of original spasm and anoxemia for the distal.

Only one patient in this group was seen with condition of original spasm and anoxemia for the distal. Only one patient in this group was seen with condition of original spasm and anoxemia for the distal. Only one patient in this group was seen with condition of original spasm and anoxemia for the distal.

There were 41 injuries to the brachial arteries and 10 to the axillary arteries. All but one of the 41 patients had an associated nerve injury. Eleven patients were operated upon with ligation of the artery in 9 and an endoarteryorrhaphy in 2 patients. The level of ligation in these younger subclavian (either proximal or distal to the profunda brachii artery) was believed to be of no importance.

The importance of adequate exposure and mobilization of the artery proximally so that operation can be safely done, especially with regard to accidentally tearing the aneurysm and then preventing the vessel from being stressed. In the cases presented, the vessel was stressed proximally. A circular ligature, especially a cast, is considered dangerous in cases of arterial injury particularly when the artery has been ligated, until the circulation has been established. Varying degrees of aneurysm were noted in 4 cases and if persistent, was easily treated with aneurysmectomy, removal of the aneurysm and subsequent ligation of the involved nerves in the treatment of the involved extremity is stressed.

There were 18 patients with injuries of the internal artery of the arm, 8 arrived with amputation previously done. Experience with ligation of the common femoral artery has given the author great respect for this type of operation.

There were 30 patients with injuries to the popliteal artery. Of these, 22 had gangrene to such an extent that amputation was required in 13 but 1 patient. Eleven of the 21 who had undergone amputation, had associated fractures. Of the 3 patients who later required amputation, gangrene developed in 1 who later required amputation or repair of the popliteal artery were present in 4 cases and in 1 patient was done in all. The resulting distal damage was so severe that all but one required amputation above the knee. Of the 21 amputations, 20 were performed above the knee joint and 1 below with very few stamps resulting in 6. Two patients who had but incisions to relieve pressure on collateral vessels were more fortunate and obtained longer amputations.

There were 13 patients in whom secondary hemorrhage was severe enough to require secondary exploration, or even death. These ligation and amputation, or even death. These ligation and amputation, or even death. These ligation and amputation, or even death.

hours. The author strongly favors the Henle Coenen test to determine the desirability of an anastomosis or venous graft. In all cases in which proper attention was paid to the presence of back bleeding from the distal segment, no difficulty ensued if this was obtained. This is not as valid in early stages in which there may be spasm and thrombosis in the collateral vessels. These elements are then evaluated with difficulty.

LEROY J. KLEINSMARKER, M.D.

Mustard W T: The Technique of Immediate Restoration of Vascular Continuity after Arterial Wounds. *Ann. Surg.*, 1946, 124, 46

When confronted with the problem of revascularizing the dangerously ischemic limb one is at once impressed by the unsolved problems in anatomy, physiology and pathology. It is therefore, essential to define the extent of ischemia affecting the wounded extremity. The dangerously ischemic limb is one which has been deprived of its blood supply to such an extent that vital processes no longer take place and gangrene results. The forerunner of this state is ischemia, and whether the ischemia progresses to recovery or not depends upon the volume of blood the limb receives, the pressure at which it is delivered, the length of time the ischemic state has existed, and the metabolic demands of the limb itself. It is only by a consideration of the general condition of the patient, the time interval and both the function and appearance of the limb that the degree of ischemia can be determined.

The variability of the circulation through the main and collateral channels renders dogmatic anatomic statements worthless. Even though the distal pulses are absent it is reasonably certain that a limb will survive if active movement of the digits is present and the digital skin has some warmth, some sensation, and is not of an unnatural color. If however, active motion of the digits is no longer present and the digital skin is cold, insensitive and of an unnatural color, then the limb is dangerously ischemic.

Active surgical interference is to be avoided when possible, if recovery of the limb is to be expected. In the dangerously ischemic limb however operation becomes a matter of some urgency whatever the local arterial lesion. In the absence of arterial spasm and of occlusion of the vessel by extravascular compression the type of surgery is limited to ligation or some attempt at re-establishing the circulation.

Ligation of the main vessel removes the hazard of further bleeding but does little to improve the blood supply of the limb. Experience has shown us that it is the procedure of choice in certain circumstances particularly as a lifesaving measure, and if heparinization is impractical. The administration of heparin requires qualified supervision including careful nursing and repeated estimations of the clotting time. It is contraindicated in multiple wounds and in wounds involving the cranial, pleural or abdominal cavities.

Ligation is also to be used if the limb has been avascular longer than 10 hours. The survival time

of avascular tissue has been investigated by many observers and the general view (with which the author's opinion coincides) is that if warmth to the limb is avoided skin will survive 24 hours, muscle 6 to 10 hours, and nerve a shorter period.

If trauma has been extensive, ligation will be in order however experience with traumatic amputations and with crush injuries would lead one to believe that no attempt at revascularizing a crushed limb should be made until more is known of this pathological condition.

Ligation is also the procedure of choice in the upper extremity. The collateral circulation in the arm is rarely sufficiently damaged to warrant anastomosis of the main vessel.

Re-establishment of the circulation in the dangerously ischemic limb is a practical procedure and may be accomplished by any of the classical methods. The author discusses the procedure he uses, stressing the indications for the use of inert materials and the technique involved in placing the tube in the arteries. He also discusses the difference of technique in the operative procedure for anastomosis of the vessels, the technique in complete division, the technique in incomplete division and traumatic thrombosis along with the postoperative care and the technique of secondary operations when they are indicated. He summarizes the data of 15 patients upon whom immediate restoration of vascular continuity was undertaken after they had acquired arterial wounds and gives the following summary of his experience.

In the dangerously ischemic limb re-establishment of the circulation by artificial anastomosis is practical under conditions in which heparinization is possible. The technique of the operation is simple but postoperative care is difficult. The operation has been performed 15 times with heparin, thrombosis does not occur in the tube if the clotting time is kept sufficiently elevated. Careful administration of this anticoagulant with repeated estimations of the clotting time is necessary to insure success. During the critical period the blood loss must be carefully considered and the blood pressure must be maintained by repeated transfusions of whole blood. The limb must be elevated to prevent muscle edema, warming of the limb is to be avoided and care must be taken with dressings. The tube may be left safely in the vessel up to 6 days. The second stage of venous graft has been performed 6 times, the nonsuture method twice and the suture method 4 times. Other factors being equal the success of the graft is in inverse proportion to its length. Following venous transplantation heparinization should be continued for at least 4 days.

A rigid tube is preferable to a venous graft as a temporary arterial bridge in acute ischemia of the limb. The results of this type of anastomosis have not been impressive and success has been an unusual achievement in war surgery in the Forward Area. It is, however, only a beginning in a new field and its application to elective arterial surgery may be of some importance.

PAUL MICHELLI, M.D.

Serralle, M: Thrombosis of the Iliac Arteries and Bifurcation of the Aorta (A propos des thromboses arterielles des iliaques et du carrefour aortique) *Rev chir Par* 1946 63: 227

The treatment of arteritis comprises two procedures (1) resection of the thrombosed segment which serves as a source of vasoconstricting reflexes and (2) section of the sympathetic lumbar chain supplemented, if necessary by splanchnicectomy or left suprarenalectomy.

In the first series (3 observations) the author performed only sympathectomy with or without splanchnicectomy. In each instance a secondary arteriectomy of the involved iliac artery was required. The first stage of the operation was not followed by great relief and the patients had to submit to a second operation.

Therefore, in the second series (4 cases) the author performed iliac arteriectomy and complete lumbar sympathectomy in one stage. All 4 patients stood the operation well.

The author points out that sympathectomy is indicated in arteritis only if a thrombosed segment can be located.

As to the technique, the author advocates the so-called progressive section suture. The first 4 lumbar ganglia are removed.

Obiteration of the external, or the common iliac, artery does not give as grave a prognosis as the obiteration of the femoral, popliteal, or posterior tibial artery. JOSEPH K. NARAT, M.D.

Catalano, G: Intra-arterial Injections in the Treatment of Endarteritis Obliterans (Le infarto intra-arterioso nel trattamento dell'endarterite obliterante) *Ann. Ital chir* 1946, 23

Because intra-arterial medication has a direct action on the sympathetics the author advocates its

use in endarteritis obliterans. In a study of 7 patients, 4 of whom had received an intra-arterial mixture of acetylcholine and padutin, while the remaining patients were treated with intra-arterial nicotinic acid, favorable results were obtained in all cases. Not only was there a disappearance of pain in the part involved but there was a rapid appearance of a line of demarcation in gangrenous cases. Rapid healing following removal of the gangrenous part, and an increase of cutaneous temperature, confirm the beneficial effect derived from this form of treatment. This intra-arterial therapy is better tolerated than treatment by the subcutaneous or intravenous route and there are no contraindications.

In the acute crisis of endarteritis obliterans gangrene can be prevented by the arterial injection of acetylcholine, padutin, and nicotinic acid, and if gangrene is present it will be arrested with evidence of a line of demarcation.

The technique is simple. After finding the position of the femoral artery, a fine needle attached to a 10 c.c. syringe is inserted through the skin, 1 to 1.5 cm. below the arch of the femoral vein. The femoral vein is entered after the pulsation of the vessel as the needle is felt and the solution is injected slowly. The patient experiences a severe burning pain, and an intense vasodilatation with a rise of skin temperature, first up to the knee then down the leg.

With the intra-arterial injection of nicotine acid no pain is felt; however, in the 3 patients so treated, hyperemia was not evident. Although there was an increased pulse rate for a few minutes, the fall in blood pressure was not great. The author cannot evaluate which of the two treatments is better and he therefore advocates a combination of the two, giving daily injections for the first 5 days, followed by 10 more injections given on alternate days.

ARTHUR F. CIPOLLA, M.D.

SURGICAL TECHNIQUE

OPERATIVE SURGERY AND TECHNIQUE POSTOPERATIVE TREATMENT

King, L. S., and Myers, H. C.: Use of Routine Bed Exercises following Major Surgery. *South Surgeon* 1946 12:36

Up to the year 1939 little effort was expended toward the prevention of postoperative complications due to bed rest. Turning patients or changing their position in bed were the only routine measures employed. During 1939 one of the authors attended a series of lectures by R. Watson Jones of England. Mr. Jones stressed to each patient the need for active exercise of all available joints and muscles and the author noted that the patients of Jones had less osteoporosis, joint stiffness and adhesions and better muscle tonus and morale than the average patient immobilized in plaster.

The following routine was then begun in all patients with casts, and was used later with slight changes, as a routine procedure in all surgical cases.

The patient should (1) turn himself in bed each hour immediately following reaction from anesthesia (2) take twelve deep breaths, filling the lungs completely every 3 hours and (3) exercise actively and vigorously every joint of the extremities for 5 minutes every hour (This was accomplished by active flexion and extension of the hips, knees, ankles and toes adduction and abduction of the shoulders flexion and extension of the elbows, pronation and supination of the forearms and flexion and extension of the wrists and fingers.)

Much time and effort must be expended in repeatedly instructing patients in these routines, as simply writing orders for exercise or routinely instructing the patient to take exercises is inadequate.

Nurses must be admonished to see that all patients carry out the exercises in a satisfactory manner. The surgeon must, by repetition demonstration and insistence again and again impress each patient with the necessity for complying religiously with these orders. Some patients fail to co-operate in spite of all these measures.

The authors believe that patients who adhere to this régime faithfully convalesce rapidly. In many patients the results are intangible. There may be an improved sense of well being improved morale, more apparent resistance to disease and a greater determination to recover.

The authors review their series of 1,476 major operations on 1,000 patients from January 1, 1939 to January 1, 1946. For comparison they reviewed 150 major operations performed on 123 patients from January 1, 1938 to January 1, 1939. There were 2 cases of postoperative thrombophlebitis among the 123 cases in 1938, an incidence of 1.6 per cent. There were 8 cases, an incidence of 0.79 per cent (a decrease of nearly 50 per cent) among those operated upon

from 1939 to 1946. Two of the 8 could not be persuaded to exercise properly.

One case of wound disruption occurred in 1938, an incidence of 0.81 per cent. There were 3 cases in the second group, an incidence of 0.48 per cent. In none of these cases could the active exercise be held responsible for the disruption.

Six cases of pulmonary complication (4.8%) occurred during 1938 and 16 cases (1.5%) during the subsequent period, a decrease of 69 per cent. The end result was fatal in one-half of the patients operated upon during 1938 and in one-fourth of those operated upon in the second period.

One case of hemorrhage was found in 1938, and 6 cases in the later series—a decrease in incidence from 0.81 to 0.59 per cent. In no case was there any evidence that postoperative exercises caused hemorrhage.

Wound hematomas were not numerous enough to be significant. There were 30 deaths in the entire series of 1,132 patients operated on consecutively from January 1, 1938 to January 1, 1946. Twenty-six autopsies were done and in no case was the death attributable to exercises in bed. For the 1938 series the death rate was 4.8 per cent and for the later series 3.3 per cent, with an overall mortality of 2.6 per cent.

The authors review some of the literature and stress the value of early ambulation and exercises in bed.

The reports of most authors were very favorable to early postoperative activity with certain exceptions in which a note of conservatism was expressed. The experiences of those who have followed the treatment of early ambulation or bed exercises have been very satisfactory.

The authors believe that early postoperative activity is justified by the increased rate of venous and lymphatic return, accelerated wound healing, lessened pulmonary complications, and improved patient morale.

The degree of activity must depend on a number of things including the gravity of the operation, the suture material used, the presence of local infection or ischemia of the tissues, and upon the judgment of the surgeon.

The authors are still carefully selecting their cases for early ambulation. However they believe that definite benefits are to be had from postoperative bed exercises alone, and that they may be practiced as outlined in almost every case without regard to suture material used or the severity or type of operation.

RONALD R. BRIDLOW, M.D.

Spence, H. Y., Evans, E. L., and Forbes, J. C. The Influence of a Special High Protein Diet on Protein Regeneration in the Surgical Patient. *Ann Surg* 1946 124: 131.

A negative nitrogen balance usually occurs postoperatively. This is correlated with loss of weight.

prolonged wound healing, and extended convalescence. A positive nitrogen balance unquestionably can be instituted in these patients by the use of intravenous substances such as amino acid mixtures, plasma, and whole blood. Most of the work on protein replacement therapy has centered around the substances which can be given intravenously. The authors have attempted to shift the emphasis to a diet that can be given orally and to determine the value of inexpensive protein material which can be made readily available to surgical patients. In spite of the controversy over whether administered protein is assimilated during the catabolic phase following traumatic injury or surgical operation these diets were supplied soon after surgical operation.

Nine suitable surgical patients were considered in this report, and the dietary period was started from the third to the twentieth postoperative day. Clinical summaries of several illustrative cases are given.

The diet was made up of 150 gm. of dehydrated beef and liver protein mixture, 150 gm. of powdered whole milk, 50 gm. of corn oil, 150 gm. of dextrin-maltose, 35 gm. of chocolate and 1,000 c.c. of water (plus vitamins A, B, C, and D and iron). This allowed a total intake of 3,000 calories each 24 hour period. The diet was given in liquid form with the insoluble material in fine suspension. Several patients had to be tube-fed for the first few days. Frequent feedings during each 24 hour period were employed. Blood plasma protein determinations were carried out at the beginning, after from 3 to 4 days and at the end of each period. The nitrogen intake could be calculated from the volume of diet administered. Daily urine and fecal nitrogen were determined, and the nitrogen balance was calculated. Total circulating plasma and protein hemoglobin were estimated from the blood volume. Each patient was studied at least 7 days.

Nitrogen retention was good in all cases and averaged, in some subjects, over one-third of the nitrogen intake. Positive nitrogen balance was established in all patients studied. In cases in which malnourishment and anemia were prominent, hemoglobin, plasma protein, and tissue protein formation paralleled the results of Robscheit Robbins with hypoproteinemic dogs; that is, for every gram of plasma protein formed, 2 to 4 gm. of hemoglobin and 10 to 30 gm. of tissue protein were formed. Well nourished patients in whom blood loss was prominent used a greater percentage of the retained nitrogen for plasma protein and hemoglobin formation. Protein regeneration tended to be more marked in the tissues in which competition was greatest for the available amino acids.

Blood regeneration in cases in which acute infection was present revealed suppression of hemoglobin formation even to the extent of hemoglobin loss, and even though nitrogen retention was quite satisfactory. Plasma albumin and globulin regeneration was variable although it tended to be suppressed. Some cases, however, manifested accelerated plasma globulin formation in the presence of infection.

The authors' results in relation to plasma protein concentration and plasma volume are in accord with those of Lyons, Madden, Whipple and others. Little correlation could be established between plasma protein concentrations and plasma volume, and in turn, total circulating plasma protein. Plasma protein and hemoglobin determinations per se do not reflect plasma protein and hemoglobin regeneration. Both values tend to show the same directional shift, but much variation is apparent.

The authors believe that it is feasible to administer a high protein, high caloric, high vitamin diet in liquid form in selected postoperative patients. This type of diet is well utilized and probably could be used to advantage in some cases in which more expensive modes of nitrogen intake are contemplated. The ease in determining the protein intake of this uniform liquid diet facilitates nitrogen balance studies.

ROBERT R. BAZZOW M.D.

Anderson, S. and Norinder, E.: Postoperative Blood Changes with Regard to Shock. *Acta Chirurgica* 1946 94:320

Eight varieties of blood tests were performed routinely during the first 3 postoperative days in a series of 73 patients subjected to one of the following types of surgery: gastric, gall bladder, thyroid, thoracoplasty, breast, renal, laparotomy or minor surgical repair. The purpose of this investigation was to find any changes in the blood which might serve as an indicator of shock. The blood tests were serum CO₂, serum Cl⁻, total base, serum protein, serum potassium, serum lactic acid, hematocrit, and blood sugar. Except for statistical elevation of lactic acid and sugar the other postoperative tests showed no significant change. The rise in blood lactic acid appeared to be directly proportional to the degree of tissue laceration caused by the operation.

In 3 cases resulting in death, the values of serum lactic acid were very high, indicating a relationship of the latter to shock. The postoperative increase in blood sugar was described as a reaction of the sympathoadrenal system and hence involved in the early compensatory mechanism of shock.

Because hematocrit and serum protein showed insignificant variation, the authors believed that the increase in capillary permeability and the fall in serum protein were phenomena of the late phases of shock. Surgical operations failed to cause changes in the cation content of the blood, and cannot be relied upon to predict the onset of shock. Depletion of alkali reserve was not observed in any case. Neither did the postoperative acidosis parallel the increase in lactic acid which proves that the latter was a factor of minor importance in early shock.

BENJAMIN G. P. SALTZBERG M.D.

Davis, J. S.: Present Evaluation of the Merits of the Z-Plastic Operation. *Plast. Reconstr. Surg.* 1946 1:26

The author sums up in a general way his personal experience with the Z-plasty. The ideal place for a

Z-plastic is in those instances in which the skin is of normal texture cases in which a web exists in certain cases of partial syndactylism and sometimes cases in which congenital grooves appear around the fingers, arms, toes, and legs. In the vast majority of cases however the Z-plastic operation is used to correct the scar contracture deformity which occurs for the most part as the result of healed burns.

The preliminary preparation includes first, an adequate evaluation of the general physical condition. The author states that a great many of these scar contractures are operated on much too early and the failure of the Z-plastic results from the inopportune selection of time rather than from an inherent fault in the procedure. Local infiltration lowers local resistance to infection interferes with circulation, and retards healing.

The operative procedure includes, first marking out the lines of incision and attempting in so far as possible to create a 60 degree angle between the central and arm lines of the Z. An angle of 30 degrees can be used and the selection of this angle should depend in part at least on the elasticity of the scar infiltrating the surrounding skin on the thickness of the flaps on the location of the contraction and the contour of the part.

After the incisions are made and the flaps are mobilized and the underlying scars excised the bleeding is carefully controlled. The flaps are then shifted and sutured. A pressure dressing is applied. This includes 3 per cent xeroform ointment covered by dry gauze and a sterile seasponge some waste and elastic adhesive plaster in addition to a soft bandage. The loose stitches are removed on the third or fourth day and the remainder are removed by the tenth day. Massage is started after 3 weeks and continued for several months.

A Z-plastic may sometimes be used in series rather than singly. They can be used individually or they can be connected one with the other. The author believes that multiple Z-plastics are being used much less frequently than they should be. Occasionally after a period of 6 months when the tissues have been softened and the circulation improved by massage, the same area can be further relaxed by a similar procedure. This is particularly useful in growing children.

Some of the advantages of this procedure are that it is simpler than other methods in certain cases tissues are successfully utilized which would otherwise be discarded the appearance compares favorably with other types of reconstruction additional scarring of unscarred areas is avoided and contractures can be permanently relieved.

LOUIS T. BYARS, M.D.

Zilliacus, H.: The Results of 5 Years Treatment of Thrombosis and Pulmonary Embolism at a Series of Swedish Hospitals during the Years 1940 to 1945. *Acta med scand.*, 1946, suppl 171 p. 13.

The author studied the problem of thromboembolism in Sweden by critical analysis of the hospital

records of 14 institutions and by personal follow up of 765 cases traced from the charts. The material embraced the years from 1940 through 1944 the era of heparin and dicumarol therapy and was compared against that of the earlier years of conservative therapy and bed rest.

The incidence of thromboembolism in these years was from 0.37 to 0.51 per cent among all types of cases. Compared with the earlier statistics the latter incidence was less by almost one-half. However the death rate from pulmonary embolism determined on a basis of the total number of thromboembolic patients has remained rather stationary. Most of the cases of pulmonary embolism occurred in thrombotic patients who were treated only by conservative therapy. Cases of pulmonary embolism occurred rarely in patients receiving heparin and/or dicumarol therapy. Since 1941, the mortality rate from thromboembolism in Swedish surgery was reduced to 1 per 1,000 and in obstetrics and gynecology to 0.1 per 1,000 patients.

The number of patients with thrombosis in the lower leg only and the number in whom the disease process progressed to the thigh were dependent on the type of therapy. Five of every 6 patients given conservative therapy suffered extension of the disease into the thigh whereas in those who were given specific therapy the process was confined to the leg in every second case. Further, as a result of heparin therapy disappearance of the acute thrombotic symptoms was rapid as compared with the average of 31 days of elevated temperature in patients who were treated conservatively. Spread of the thrombosis to the other leg occurred in 30 per cent of the patients treated conservatively while in those given specific therapy the incidence of spread was only 1.4 per cent. The complication of pulmonary embolism was 13 times more frequent in the conservatively treated cases and 9 of every 100 patients died whereas only 1 of every 200 thrombotic patients given specific therapy died.

Sudden pulmonary embolism without signs of thrombosis was noted in 282 cases. In 114 of the latter thrombosis was not diagnosed clinically until the embolism occurred. On postmortem examination of 60 of these cases fresh thrombi in the deep veins of the lower extremity were found. It was the author's contention that the latter fatalities could have been avoided by daily careful examination of the lower extremities and the early institution of specific therapy. Among 103 patients with sudden pulmonary embolism treated with heparin and dicumarol, no deaths resulted and only 31 were found to have any swelling of the legs as a post-thrombotic sequela. In another series of 65 cases of pulmonary embolism treated conservatively there were 21 deaths following repeated attacks of embolism. Hence, every patient with pulmonary embolism should be immediately heparinized in order to prevent the reformation of a thrombus at the site of first dislodgment and to counteract the growth of the embolus.

In the follow up study of patients who had recovered from deep vein thrombosis the sequelae after thromboembolism were classified as follows: (1) no signs or symptoms, (2) subjective symptoms only—tenderness an aching pain cramps heaviness, (3) signs and symptoms after exertion—swelling, discoloration (4) chronic swelling of the lower leg or some part of it, (5) chronic discoloration, eczema, or varicose veins, (6) leg ulcers (7) swelling of the thigh after exertion, and (8) chronic swelling of the thigh.

The sequelae were much worse in the cases in which the thrombosis had extended to the thigh than in those in which it was restricted to the leg. Anticoagulant therapy was twice as favorable from the standpoint of sequelae as conservative therapy. In the cases receiving the latter, symptoms developed rapidly within a year after the acute attack. The majority of these patients were found to be in classes 4, 5 and 6 suffering from chronic swelling discoloration, varicose eczema, and leg ulcers. The average classification in the 184 cases treated conservatively 1 to 5 years after recovery was class 5. The sequelae in patients with deep vein thrombosis of both the leg and calf were equally severe with many in class 5. The post thrombotic sequelae in patients with involvement of the calf or leg treated with heparin were mild and more than half were in class 1.

Chronic swelling discoloration, varicose veins, and ulcer must be regarded as a direct continuation of the disease process after subsidence of the acute thrombotic process. During the latter period a thrombus originates in one of the small veins of the calf and then expands in the direction of the blood stream. From venographic observations it is known that the small vein thrombi continue to grow and extend into larger veins until they finally fill these veins. The only 3 large deep veins in the lower leg, the anterior tibial vein, the posterior tibial vein, and the peroneal vein, flow into the popliteal vein which continues on into the thigh as the femoral vein and is the only deep vessel of the thigh. When the thrombotic process has involved the popliteal vein, stagnation occurs as the result of the obstruction of the remaining deep veins. Thereafter the superficial venous system must compensate for the return venous flow. This added burden on the superficial veins accounts for the discoloration, edema, and varicosities and depends upon the degree of involvement of the popliteal and femoral veins.

It is the author's belief that the surgical treatment of deep venous thrombosis by vein ligation, femoral, iliac or inferior vena cava, is less satisfactory than by treatment with anticoagulants. The only advantage that operation offers is an elimination of the risk of pulmonary embolism. The same risk can be eliminated also by means of heparin. Furthermore, heparinization has an added advantage because of its action on clinically undiagnosed thrombi. Finally postoperative sequelae result from the ligation of a main stem vessel and this can be avoided by means of the use of heparin.

A detailed report was made of the cases of deep venous thrombosis at the Mälarstad Hospital in Sweden during the period from January 10, 1933 to September 9, 1945. Of 16,495 patients admitted 304 developed venous thrombosis and pulmonary embolism. Diagnosis in every case was confirmed by venography and treated immediately with heparin. The latter series was compared with 364 cases of deep vein thrombosis at the same institution from 1919 to 1938 when conservative therapy was in vogue. It was found that 18 per cent of the conservatively treated patients died whereas only 14 per cent of the heparin treated patients died thus the mortality rate from pulmonary embolism was one-tenth as large when specific therapy was given. The average number of hospital days in bed with conservative treatment was 40, while with specific therapy it was 4.7 days. Follow up examination revealed that 60 of the 76 heparin treated patients recovered completely without any sequelae. It was also noted that when heparin therapy was started upon early diagnosis the disease was limited to the lower leg spread was prevented, and pulmonary embolism and thrombotic sequelae were avoided.

For the early diagnosis of thrombosis it must be remembered that the disease process begins in one of the following areas: the lower leg calf, the plantar surface of the foot the adductor region of the thigh, or the pelvic veins. The physician should not wait for an elevation of temperature but should always take the initiative and examine and palpate the legs of a bed patient long before swelling becomes manifest. Nurses and patients should be instructed to report any pain in the extremities. The deep veins of the leg are best palpated when the patient lies on his back with his knees elevated. The examiner stays at the foot of the bed and simultaneously palpates the muscles of the calves of both legs. An increase in consistency can readily be determined by this method. As the thrombotic process advances the findings become more positive. Thrombosis in the plantar veins is determined by tenderness in the sole of the foot. The adductor region in the thigh are examined in the same manner as are the calves of the legs. Rectal and vaginal examination should be done to detect thrombosis of the pelvic veins. The early diagnosis of thrombosis must always be followed immediately by specific therapy.

Heparin should be given at once to obtain an immediate anticoagulant effect. It should also be used in a sudden attack of pulmonary embolism. The effectiveness of heparin is due to its antithrombotic effect. The coagulation time of the blood is prolonged by the intravenous injection of from 125 to 150 mgm. of heparin 4 times daily. Active movements are begun with the first injection. Deep breathing exercises and free movements in bed are enforced. When the temperature becomes normal the patient is allowed to sit up in a chair and heparin is reduced to 3 doses—100, 50, and 100 mgm.—per day. When the patient is allowed to walk an elastic

bandage is applied from the foot to the knee and the heparin is further reduced to 2 doses a day 100 and 125 mgm., respectively. Increasing activity is given once daily. After discharge from the hospital, the patient is instructed to wear an elastic bandage as long as discomfort or swelling exists. The patient is also warned not to overstrain the leg. If the primary illness confines the patient to bed heparin must be continued for a longer period while the patient is in bed.

Dicumarol exerts an anticoagulant effect by inhibiting the formation of prothrombin. The effect is obtained only after from 12 to 48 hours of administration and the degree of inhibition varies in different individuals. The prothrombin time is the index of the amount of dosage. On the first and second days an average of 0.25 gm. of dicumarol is required. When heparin and dicumarol are combined in therapy the heparin should not be discontinued until the dicumarol effect is obtained as determined by the prothrombin time.

ANTISEPTIC SURGERY TREATMENT OF WOUNDS AND INFECTIONS

Smyth, H. F.: Anthrax: Its Diagnosis and Treatment. *Occup M* 1946 8

There were 408 reported cases of anthrax in this country from 1939 to 1943. Of these 316 occurred in tanneries or woolen mills in 6 northeastern states. The disease was diagnosed early and the patients were properly managed by trained personnel with a resulting relatively low mortality. The remaining patients were usually seen by different physicians with little or no previous experience in the recognition and treatment of anthrax. The latter group suffered a higher mortality incidence.

This article was prepared for the benefit of those who on occasion may encounter a case of anthrax. The salient features of the incidence, clinical diagnosis and bacteriology were discussed, and emphasis was placed on the necessity of instituting treatment promptly even before the diagnosis can be substantiated. The oftentimes fatal bacteremias and malignant forms of anthrax can thus be aborted.

Local treatment has been condemned generally as being unnecessary and even undesirable. Since the advent of the use of serum at the turn of the century the mortality rate has been reduced but because of alarming reactions other agents have superseded the use of serum. One of these has been neocarphenamine either alone or combined with serum. The author recommends the former course, since, in 62 instances out of a single fatality occurred when the arsenicals were used alone. A mortality rate of 4.7 per cent resulted in 64 collected cases when sulfonamide drugs were the sole agent. Although penicillin may prove extremely effective, too few cases have as yet been reported to allow any conclusions.

DAVID H. LYNN M.D

Ellingson, H. V., Kadull, P. J., Bookwalter, H. L., and Howe, C.: Cutaneous Anthrax. *J Am M Ass* 1946 131 1105

The early treatment of anthrax was given by means of cautery or excision, and was attended with a fatality rate ranging from 30 to 60 per cent. After the introduction of Schlobov's antianthrax serum, radical local treatment was gradually abandoned with improvement in the recovery rates. Lucchese and Gilderleeve reported 67 cases treated with serum and neocarphenamine, or both without a single death. Gold reported 60 cases of cutaneous anthrax treated with serum, neocarphenamine, and various sulfonamides with only 1 death.

The treatment of anthrax with penicillin was suggested in 1941 when Abraham and his associates reported the in vitro sensitivity of the *Bacillus anthracis* to this antibiotic.

The authors give a report of their observations on 25 consecutive cases of cutaneous anthrax. The *Bacillus anthracis* was recovered from the blood of 3 of the patients. All were treated with penicillin and 3 were treated with sulfadiazine in addition to the penicillin. All recovered uneventfully. They were under close medical surveillance at all times and general treatment was initiated while the lesions were in relatively early stages.

The lesions were located for the most part on exposed areas of the body.

HARRY W. FINE, M.D.

Gay, E. C.: Skin Dressings in the Treatment of Debrided Wounds. *Am. J Surg* 1946 72 213

A series of 101 cases of the application of split thickness skin grafts is presented and the relationship of this work to general surgery and to orthopedic surgery is discussed. Six of the cases are reported in brief with photographs. Successful takes of the grafts were obtained in 87 per cent of the cases.

The entire effort is based on an attempt to convert large tissue defects received in war injuries into rapidly healing closed wounds which shortens the patient's period of hospitalization and convalescence, and returns him early to limited or full military duty or allows for more comfortable evacuation to the Zone of the Interior.

In conclusion the author states that the optimum time for the use of split skin grafts as a "skin dressing" to large tissue defects, received as war injuries, is between the fifth to the tenth day after injury.

These grafts are practical in the presence of excessively exuding wounds, and also in the presence of mild surface infection. They may be used in combination procedures involving drainage of dependent areas, partial secondary closures and skin grafting.

The application of dressings at forty-eight-hour intervals offers the greatest opportunity to combat excessive exudation which is a predominant feature of massive war wounds. This technique gives the greatest protection to the grafts applied.

Grafts used for this purpose should be very thin since the thin split thickness graft shows a higher percentage of complete takes in the presence of

excessive circulation, a moderate defect on than the deep intermediate grafts.

The intermediate grafts are less likely to be com- secondarily infected and heal without delay.

Failure of these grafts to take is attributed to retention of foreign bodies and/or excessive infection as a result of deep penetration of wound dirt. However, if special antiseptic primary closure is followed by covered and sutured margins of the wound.

These grafts are not suitable for use in facial injury but serve as an adjunct to general and orthopedic surgery in the case of war wounds which involve massive loss of skin surface.

The time necessary for the consummation of the work lies within a 30 day period.

The potentialities of the use of these flaps in grafts applied early in the treatment of war wounds have been fully transcribed to the medical services of our practice.

Robinson, D. W., Stephenson, K. L., and Padgett, E. C.: Loss of Coverage of the Penis, Scrotum and Urethra. *Plast. Reconstruct. Surg.* 34: 35.

The authors state that for the reconstruction of the testis, penile skin cover, a pedicle flap is necessary. In a case in which the injury is extensive, a flap from the scrotum can be used. A flap cut out higher than necessary to take the perineal area is to cover the defect with a circular bearing graft. Columns of cutaneous grafts are put on in a "fish tail" fashion. In the case of a large loss of skin, a free flap is necessary.

When the penis and scrotum are denuded of skin grafts should be used as a second step. At the same time, the testis is placed in a testicular sheath and the urethra is closed. The flaps are taken loose from the chest and returned to each of the areas to create a new skin. The flaps are then sutured in place. In cases in which a portion of the urethra is missing, it is necessary for the urethra to be created by the use of catgut for the urethra. The urethra is then covered by the skin flap. The urethra is then covered by the skin flap. The urethra is then covered by the skin flap.

The authors state that the use of a flap from the scrotum can be used. A flap cut out higher than necessary to take the perineal area is to cover the defect with a circular bearing graft. Columns of cutaneous grafts are put on in a "fish tail" fashion. In the case of a large loss of skin, a free flap is necessary.

The authors state that the use of a flap from the scrotum can be used. A flap cut out higher than necessary to take the perineal area is to cover the defect with a circular bearing graft. output is improved. When lactate solution is the only electrolyte given there may be a tendency to overcorrection of the acidosis even to the point of clinical alkalosis, as noted in some of the cases. Electrolyte therapy should consist of a mixture of lactate and saline solution, or bicarbonate and saline solution. Oral administration should be started as soon as vomiting has ceased.

Replacement therapy in burn shock should be directed toward the restoration of all deficits in the circulating blood. These include red cells, plasma proteins, water, and electrolytes. Whole blood transfusions fulfill these requirements more closely than any other single agent. The presence of anemia is a recognized indication for blood transfusions during the healing stage of burns but when hypoproteinemia is more severe than the red cell deficit, it is generally believed that plasma, albumin, or amino-acid infusions are indicated. The authors suggest that whole blood rather than blood substitutes, is more effective in maintaining nitrogen balance, and that a moderate excess in red cell mass may be indicated during the healing stage of severe burns. Several reasons for this stand are given:

1. When the viscosity of the blood is reduced by the depletion of plasma proteins, a moderate excess in red cell mass will increase the viscosity of the blood and thereby contribute to more normal hemodynamics.

2. As a source of protein, whole blood contains almost twice the concentration of an equal volume of plasma, since the hemoglobin content represents roughly $2\frac{1}{2}$ times as much protein as the plasma content of whole blood. When a unit of blood is given its plasma component is immediately available to augment the plasma proteins or body reserves its red cell mass if in excess of normal, represents a rich store of protein readily available.

3. Experimental work on dogs by the authors suggests that an excess red cell mass may have an immediate sparing action on body proteins by displacing plasma volume and thereby reducing the amount of plasma in wound healing. Whole blood alone failed to precipitate pulmonary edema in the experiments but this condition was encountered when saline solution was given with the transfusions.

4. Patients in this series in whom anemia was quickly corrected or overcorrected assimilated more protein given by mouth than those in whom the anemia was not controlled.

5. The patient in the process of forming a large granulating surface may have a physiological increase in his total blood volume to aid in the process of healing.

Provided whole blood transfusions are given water and electrolytes can be administered more effectively by mouth than by vein and will be absorbed in adequate amounts. Sodium chloride solution in combination with lactate or bicarbonate in combination with lactate or bicarbonate is a more rational electrolyte mixture than sodium lactate solution alone in view of the tendency to alkalosis and hypochloremia, which may result from vomiting and overalkalemia.

tion in burn shock. In general plasma losses will predominate in extensive second-degree burns while in third-degree burns, the red cell mass lost from the circulation may equal or exceed the losses in plasma volume. If the anemia of the postshock phase of a severe burn is not prevented by giving adequate amounts of whole blood in the shock period it should be corrected once recognized for delay of even a few days may be disastrous. During the healing phase of a severe burn whole blood should be administered in amounts adequate to theoretically overcorrect the anemia. When this is done the problem of nitrogen balance will be simplified. In the presence of an anemia and hypoproteinemia uncontrolled electrolyte therapy by mouth or by vein is contraindicated since it will increase cellular edema and in some cases may lead to fatal pulmonary edema.

JOHN H. MCHEMIST M D

HOWES, E. L.: Prevention of Wound Infection by the Injection of Nontoxic Antibacterial Substances. *Ann. Surg.*, 1946 124: 568.

A mixture of streptomycin (300 units per cubic centimeter) and sulfamylon (5 per cent) was found previously to be bactericidal as well as innocuous to tissues. To ascertain whether this combination was an ideal subcutaneous antiseptic and if it was capable of preventing infection in wounds several experiments were performed on rabbits. The results are evaluated in this paper.

If crushed wounds were contaminated and not treated infection always followed. On the contrary if the wounds were treated immediately infection seldom occurred, but if treatment was instituted 3 hours or later after the wound was made and controlled infection resulted. Additional injections or washings once infection occurred, did not resolve the process although the bacteria remained susceptible to the antibacterial agent. Debridement and treatment did prevent infection.

In an attempt to find an explanation, biopsies were taken of the loose connective tissues directly under the skin, and of the muscle. Microscopic examination showed that many leucocytes had already invaded the tissues and every leucocyte contained many bacteria. The most logical explanation of the failure to prevent infection after 3 hours is that many of the bacteria were no longer extracellular and were thus not reached by the antibacterial agent. While phagocytosis is helpful in combating infection yet, if the leucocyte is killed before the bacteria are destroyed the micro-organisms are free to contaminate the wound again.

Resolution of an established infection requires, in addition to a potent bactericide, adjunct chemotherapy—to dissolve sloughs to expose leucocytes and to provide chemical drainage. A word of caution must be said about the clinical use of these antibacterials to prevent infection in wounds. They and the method of their employment must not be substituted for good surgery. Necrotic tissue and infected foreign bodies should always be removed.

Other antibacterials can be substituted for sulfamylon and streptomycin. Injection of antiseptic substances locally points to new possibilities in the local treatment of wounds. DAVID H. LYNN, M.D.

Egoroff, B.: New Lingual-Oral Method of Administration of Penicillin. *Vrachebnoe Delo* 1946, p. 355.

Hydrochloric acid and intestinal bacteria inactivate penicillin administered through the digestive tract. The author avoids this drawback by applying penicillin to the tongue. Saliva, and especially ptyalin, do not destroy penicillin. One thousand Oxford units of dry penicillin are dissolved in 1 c.c. of water normal saline or 40 per cent glucose. One drop of the solution contains 5,000 units of penicillin. One to 2 drops are applied to the tongue every 30 to 60 minutes and the patient is instructed not to swallow but to distribute the solution with the tongue over the palate lips and gums. Patients prefer such a procedure to frequent injections. If larger doses are required, 10 drops may be administered at once.

If desired, 100,000 units of penicillin may be dissolved in 3 c.c. of alcohol, which irritates the mucous membranes and creates hyperemia, which in turn stimulates absorption.

If the tongue is coated, it should be cleansed with a toothbrush before the administration of penicillin.

Stomatitis, gingivitis, and pharyngitis do not form a contraindication to a local application of penicillin. Some patients prefer a sublingual administration of penicillin but the presence of a relatively large amount of saliva in that region retards the absorption of penicillin.

While absorption of penicillin from lozenges is very slow the drug reaches the circulation very promptly after its application to the tongue in liquid form. Penicillin is absorbed by the tongue, the lips, the gums, the mucous membranes of the oral cavity, the palate tonsils, pharynx, and possibly also the esophagus. The three routes of absorption are through the veins, the lymph vessels, and the perineural and endoneural paths.

JOSEPH K. NARAY, M.D.

Rowe, A. H.: Delayed Healing of an Abdominal Wound Due to Food Allergy. *West. J. Surg.*, 1946 54: 3-5.

The author reports the case of a 13 year old boy who had cramping abdominal pain associated with other gastrointestinal symptoms for a period of 5 years. Appendectomy followed by failure of wound healing and a recurrent serosanguineous discharge, had been performed 3 1/2 years before his referral to the author. After 2 years another surgeon reopened, curetted, and resutured the wound with equally unsuccessful results. There was a family history of allergy. Physical examination was negative except for moderate diffuse abdominal tenderness and a membranous bulging fluctuant wound in the right lower quadrant. The usual scratch tests were nega-

tive, and there were no abnormal reactions following cutaneous and subcutaneous implantations of various suture materials. Gastrointestinal x-ray studies, wound cultures, and histological studies were not made.

The patient was placed on an elimination diet. Within 2 weeks the gastrointestinal symptoms disappeared, the wound healed and has remained healed for 1 1/2 years. Subsequent studies indicated an allergy to milk which disappeared when the patient changed from a maritime to an inland environment.

The author concludes that the control of food allergy was responsible for the healing of a wound of 1 1/2 years duration and also for the control of lifelong gastrointestinal symptoms. There was no local wound treatment, no removal of any foreign substance, nor of retained sutures, no drugs or vitamins were given and there was no increased protein or caloric intake.

The assumption is made that accumulation of antibodies and allergens of the allergic foods, and/or a decrease in collagen and fibroblasts resulting from the localized allergy was responsible for the delayed healing and recurrent discharge from the wound.

It is suggested that allergy be considered as one cause for delayed healing or necrosis in wounds in any part of the body as well as abnormal sensitivity in abdominal wounds, particularly in patients with personal or family histories of allergy.

S. LEON TERNERMAN, M.D.

Leigh, O. C.: A Report on Trench Foot and Cold Injuries in the European Theater of Operations. *Ann. Surg.* 1946, 124: 301.

This article reports a detailed study of 500 of the 5,000 cases of trench foot observed at the 10th General (U.S.) Hospital, (E.T.O.) during 1944 and 1945.

Trench foot is a term used by the United States Army Medical Corps to describe the cold injury resulting from prolonged exposure to just above freezing temperatures (34 to 40°F). It has occurred almost exclusively in combat infantry riflemen who were forced into immobility by enemy action.

Frost bite is used to describe the cold injury resulting from exposure to below freezing temperatures—either of the ground type occurring in the ground forces or high altitude type, occurring in combat air crews. Immersion foot designates the cold injury resulting from prolonged exposure of the feet to cold water. These injuries are usually described as different clinical entities, although the evidence indicates that they all present similar pathological changes and can be treated identically.

The incidence varied from 3 to 50 per cent of battle casualties, depending upon near freezing or freezing temperatures, wetness, immobilization of ground forces, inadequate and ill fitting foot gear, and failure or inability to enforce strict foot discipline. Company commanders most successful in avoiding casualties required each soldier to exchange

SURGICAL TECHNIQUE

wet socks for clean dry ones and relieved a few soldiers from each group daily for a short time during combat activity.

Etiologically three factors were always present: (1) wet cold, (2) prolonged exposure in a relatively immobile position, and (3) physical activity following the exposure. Of these factors, wet cold is the most important.

In trench foot the sequence of events leading to injury are fairly constant. The combat infantry soldier is forced into immobility in a wet foxhole for a prolonged period of time. He first complains of a tingling or stinging sensation in his feet which may become quite intense. After a period of exposure the feet become numb and finally anesthetic. When the attack is ordered or he is relieved walking causes severe burning pain and on removal of his shoes the feet become swollen and warm. Many soldiers complained that their shoes were too small after several days of exposure.

The immediate reaction of the skin to cold is a blanching in color. The blanching is caused by contraction of terminal arterioles and veins. The sensation of cold appears as the skin temperatures are reduced to 35° and then to 15° C. At these temperatures the skin develops a bluish color (cyanosis) which indicates local oxygen deficiency. As the temperatures are lowered to 10° and to 8° C the bluish color changes to purple and finally to a bright red or pink. These color changes indicating excess metabolism and a lower oxygen dissociation from the blood at these temperatures. Each of the color changes may be transient or prolonged according to the degree of cold, duration of exposure and speed of wind currents. If the surrounding temperature is returned to normal after a short exposure, no further reaction will occur. If prolonged, secondary pathological reactions follow.

In first-degree injuries (36.4% based on 500 cases) the color changes and sensations encountered during exposure are quite similar to those described above. When placed in a warm environment, the foot develops a bright red flush. The larger vessels show increased pulsations for a few hours and the skin appears thicker from edema. Tingling of the feet is felt early and later itching burning or mild throbbing pain. This hyperemic or inflammatory stage subsided within 3 days (1-6 days) after which the foot assumed a normal appearance. All patients were walking without pain within 4-2 days (from 0 to 10 days) after exposure. This group of patients was returned to full duty after a short period of rehabilitation.

In the second-degree injuries (55.6%) the reaction after exposure is more severe with hyperemia pulsation of the larger vessels and throbbing pain, which may last for several days. Blisters appear and intracutaneous ecchymosis develops on the weight bearing surface of the foot and toes. The edema subsided on the average in 8.4 days (from 6 to 10 days) and was followed by varying degrees of scaling the

skin was sensitive and perspired profusely. The feet became warm and painful on exercise and in a warm environment. Exposure to cold is more comfortable for the patient. Most of these patients were returned to limited duty but many were later discharged as unfit for any kind of duty.

In the third-degree injuries (8%) the initial reaction is intense in 3 or 4 hours after the foot is placed in a warm environment. All the cardinal signs of inflammation are present—marked edema, heat, redness, and burning throbbing pain. Large blisters, intracutaneous ecchymosis and superficial skin necrosis are present. The inflammatory stage averaged 12.4 days (from 7 to 32 days) only rare cases showing persistent edema for more than 14 days. The superficial layers gradually mummified and desquamated, leaving a pink sensitive skin. On dependency the skin assumed a dusky cyanotic hue and disability during the 3 month period of observation and were unfit for further duty. One severe case required amputation of the feet. Digits were lost in 1 per cent of 500 cases.

Once hyperemia has developed treatment is directed toward preserving the superficial injured layers of epidermis which forms a tough dry protective covering of the viable layers beneath. The foot is exposed to a cool, dry environment and kept elevated on pillows. In the earliest stages of hyperemia pressure bandages over cotton decrease edema and relieve pain. Surgical amputation should never be done in the early stages except for gross secondary infection. Dry gangrene of the toes occurred in only 1 per cent of the carefully followed cases. If infection is present sulfa drugs and penicillin should be used as in any other infection. Tetanus toxoid is given in open wounds. After the edema has subsided the treatment is directed toward the prevention of foot deformities caused by atrophy of the muscles and fibrosis. Supervised exercise of the feet physiological measures and guarded ambulation should be initiated at the earliest possible moment. The use of vasodilator drugs and lumbar sympathetic block was investigated these measures did not give relief from pain and did not decrease the convalescent period. The pathological and physiological changes in trench foot are similar to frost bite but less severe. The basal germinal layer of epithelium remains intact in trench foot but is lost in frost bite.

JOHN H. MORARDT M.D.

Kling, P. F.: Erysipeloid: Survey of 115 Cases. *Lancet* Lond., 1946 2 196

The material studied consisted of 115 unselected cases of erysipeld among 2,500 cases of all types seen in the septic hand clinic at Charing Cross Hospital from May 1941 to the end of December 1945. The condition was first described in 1873 by Baker and renamed erysipeld in 1884 by Rosenbach.

The causal organism is the gram positive bacillus *Erysipelothrix rhusiopathiae* which causes erysipeld in pigs. The cutaneous form is the common

though intestinal and generalized forms have occurred. The infection results from contact with organic matter usually mammals, fish, shellfish, bones, flesh or shells but vegetable material or any form of nitrogenous products may also bring on the condition. The lesion occurred in 5 per cent of the septic hands at this clinic and was almost restricted to people employed at catering thus it was an occupational disease.

The lesion manifests itself from 2 to 7 days after the initial injury, which may be a cut, scratch, or puncture of the skin. It is characterized by a dark purple red zone, sharply defined and raised in the center of which the site of injury is often found to be healed. It usually occurs on the fingers, and from about the third to the fifth day the lesion extends peripherally the change being most noticeable toward the upper part of its distribution. After about a week the central part of the rash fades and desquamates, while the periphery continues to extend. It is common for the spread to reach (1) the palm or dorsum of the hand (2) the neighboring webs, (3) the adjacent sides of the neighboring fingers, and (4) the proximal phalanges of the neighboring fingers. The lesion appears to be commoner on the middle fingers and the thumb particularly of the right hand.

The rash is accompanied by a sensation of heat, burning and irritation of the part, which may become considerably swollen, and gives rise to a feeling of local tightness. Stiffness of the interphalangeal joints is common with resulting limitation of movement. Pain is common, especially early and becomes worse where the lesion extends, while at the same time it eases centrally. It may be throbbing, burning or smarting. There is a subcuticular extravasation of blood sometimes.

General symptoms are inconstant. Regional lymphangitis and lymphadenitis may occur. Of the 115 cases, only 5 showed lymphangitis and only 5 localized adenitis. There may be arthritis of the interphalangeal joint and this may lead to stiffness.

Erysipeloid is characterized by regressions and relapses. The average duration of the disease treated in this series was under 17.4 days but any time from 14 to 28 days is common. The variation was between 51 and 7 days. In the latter stages the lesion fades from the periphery inward. The lesion must be differentiated from erysipelas.

Erysipeloid has a seasonal incidence concurrent with epidemics of swine erysipelas and thus the greatest seasonal incidence is during the summer and early autumn. The author believes it is possible that the fly may be a vector carrying the organism from the feces of infected pigs and contaminated organic material.

Of 115 cases, 95 occurred among persons employed at catering and including housewives. The highest incidence occurred among cooks (50.8% if one considers each housewife in this class). Barmen, waiters, kitchen hands, and others account for 22.6 per cent, and fishmongers, poultryers and butchers for a

further 9.5 per cent. In this series, of the 20 persons not employed in the catering trade, 6 were infected from an animal source, 6 from a plant source, and 8 from an unknown source.

There seemed to be no special age and sex distribution.

Immunity is not conferred by one attack. Of the present patients 2 had second attacks.

The treatment is entirely medical with rest of the part as the fundamental principle. This is best obtained by not allowing the patient to work, using a high sling to keep his hand and forearm relatively immobile and applying hot wet boric dressings. The author believes that penicillin given systemically may be of considerable value although he did not use it.

LEROY J. KRAMER, M.D.

ANESTHESIA

Poe, M. F., and Karp, M.: *Seconal as a Basal Anesthetic Agent in Children: A preliminary Report. Current Res Anesth.* 1946, 25: 152.

Basal narcosis is especially useful in the management of children undergoing surgical procedures. It spares the child the psychic disturbance attendant upon the trip to the operating room and induction of anesthesia. It reduces the amount of inhalation anesthesia as much as possible and it provides a period of postoperative rest and amnesia.

Seconal, a short-acting barbiturate, was chosen for trial as a basal depressant because of its quick action and its relatively short duration. The basis for estimating dosage was the age and weight of the patient, but consideration was given to the child's general condition, body build and vigor and nervous reactivity. A calculated dose of from 0.14 to 0.15 grain (9-0.5 mgm.) per pound gave the optimum degree of narcosis. It was planned in all cases to use local infiltration, and the basal anesthesia was employed to provide a manageable patient. Whenever pentothal sodium or other supplement was anticipated, atropine sulfate was administered subcutaneously as part of the postoperative medication. Seconal is rapidly absorbed when given either by mouth or by rectum. Oral administration was employed when feasible.

Seconal was used in 22 neurosurgical and in 3 ophthalmological procedures in children ranging from 3 months to 6 years of age. The majority of children in this group were in good physical condition, the procedures being performed for diagnosis. Side effects observed were a rise in pulse rate, some decrease in respiration, and a fall in blood pressure.

MARY FRANCES POE, M.D.

McAllister, F. F.: *The Effect of Pentothal Sodium on Mean Arterial Blood Pressure in the Presence of High Spinal Cord Paralysis. Ann. Surg.* 1946, 124: 328.

The effect of pentothal sodium on mean arterial pressure in the presence of high spinal cord paralysis produced experimentally in dogs, is reported. The

increasing use of intravenous barbiturates in conjunction with spinal anesthesia, and the fact that ether is known to act unfavorably on blood pressure when the spinal cord impulses are interrupted at the level of the sixth thoracic segment or above it prompted this study.

Spinal cord transections were made aseptically in the lower cervical region between the sixth cervical and the first thoracic segments. Control determinations of blood pressure were done on normal dogs.

The author's experiments on dogs indicate that when the function of the spinal cord has been interrupted in the lower cervical or upper thoracic region intravenous pentothal sodium produces no serious depression of the blood pressure. Thus this anesthetic is quite different from ether which is known to cause a pronounced fall in the blood pressure of such animals. Experimentally then when the suprasegmental vasomotor control has been eliminated intravenous pentothal is a safer anesthetic than ether.

JOHN H. MONARDT, M.D.

Booker W. M.: Observations on the Carbohydrate Metabolism during Prolonged Pentothal Anesthesia in Dogs: The Blood Sugar and the Liver Glycogen. *Anesthesiology* 1946 7: 405

In view of the dearth of experimental work, clinical as well, on the far-reaching effects of prolonged pentothal anesthesia, it seemed important that studies in this connection be launched to determine the feasibility of prolonged pentothal anesthesia keeping in mind those effects which may tend to vitiate the recovery powers of the animal or the patient.

The work reported here was done on approximately 45 dogs. Glycogen determinations were made on livers of all animals routinely 36 to 48 hours after the period of anesthesia. In a few of the early experiments liver function tests were also performed. Animals were anesthetized with a 3 per cent solution of pentothal sodium injected into the antecubital vein. Blood sugar on 0.2 c.c. of blood was determined by the Gibson micro method which is a modification of the Folin Wu method. The Benedict method for glycogen determination was employed. The results bring to our attention the interesting point that when pentothal is administered at frequent and regular intervals a point at about 3 hours is reached when the administration falls off both in frequency and amount. One of two things is occurring: either the machinery for handling the pentothal has become embarrassed and more and more pentothal is building up in the tissues or the nervous system has become more adapted to its state of depression so that less and less amounts of anesthetic are necessary for maintenance of that depression. Full cognizance is taken of the fact that the fate of pentothal is controversial.

In the experiments reported in this paper there were a few instances in which the ureters were tied off immediately after the first injection without any difference noted in the frequency or amount of anesthetic administered throughout the period of anes-

thesia (4 to 6 hours). In one experiment the kidneys were removed entirely but the frequency and dosage did not vary from the usual pattern. This is good indirect evidence that in the dog pentothal is not excreted appreciably by the kidneys. Liver function tests tend to show that as anesthesia progressed, the ability of the liver to remove bromsulfalein from the blood is lowered. This would seem to indicate that the liver is undergoing some type of strain or taxation during the progress of the anesthesia so that its removal of bromsulfalein from the blood lags. The rise of blood sugar is in agreement with the observation of Marshall, who called attention to a mild hyperglycemia followed by a hypoglycemia in recovery phases under pentothal anesthesia. Whether or not this represents a damage or a strain on the liver may be open to controversy. It may be agreed however that something occurs in the liver to cause glycogenolysis with a resultant increase in blood sugar. Could it be that the enzyme system responsible for converting and maintaining glucose to glycogen is interfered with so that control of the liver glycogen is temporarily lost?

The influence of prolonged pentothal anesthesia on the glycogenolytic-glycogenic activity seems to be shown further in the inanition experiments. When animals deprived of food were given sugar just prior to anesthesia and were anesthetized for 4 hours it was found that the blood sugar was extremely high remained high throughout the experiment and was still high 24 hours later. It seems that the liver of the animals in the anesthetized series is unable to handle the excess glucose, even though its glycogen has been markedly lowered by deprivation of food. It may be that an explanation lies in the interruption of the glucose-glycogen pathway somewhere in the intermediary metabolism.

The high carbohydrate series of experiments was undertaken to determine whether or not good glycogen storage could withstand the depletory effect of pentothal. We see that although the livers of this series store glycogen in extremely high quantities (no pentothal experimentation) livers of animals on high carbohydrate diet (prolonged pentothal anesthesia) are markedly lowered in glycogen. It seems questionable therefore, whether or not the liver can be protected in prolonged administration of pentothal by either building up the patient with a high carbohydrate diet or injecting glucose concomitant with the anesthesia. We are of the opinion that in prolonged anesthesia glucose when administered in a very high quantity is not converted into glycogen and stored in very high quantity and preanesthetic glycogen stores are lowered by prolonged anesthesia.

MARY FRANCES FOX, M.D.

Apgar V: Experience with Curare in Anesthesia. *Ann. Surg.* 1946 124: 161

Two hundred anesthetics were supplemented by curare and the author's experiences are recounted.

In all cases the anesthetic was administered by physician anesthetist after at least 3 months of

active resuscitation. The technique of curare administration is described in detail. The curare (Intocostrin) used was found to mix freely with saline, glucose, or blood, but a precipitate with all pentothal concentrations was formed. The cases were tabulated as to type of surgery performed, type of anesthetic used, reason for the use of curare, amount of curare used, respiratory and circulatory effects of curare, and the return of reflexes.

One death was believed to be related to the use of curare and due to accidental overdose and too vigorous resuscitation.

The results obtained in the 25 ton illectomies in which pentothal and curare were administered were appreciably better than a parallel series of cases without curare. Recovery in the group who had not had curare was prolonged and marked by extreme restlessness, necessitating much more nursing care than the group who had received curare. Only 3 per cent received prostigmine in 0.5 mgm. doses and no effect was observed in these patients.

The main disadvantage to the use of curare has been the difficulty experienced in teaching the signs of anesthesia. The demand for the drug during upper abdominal operations has increased to such an extent that it may not be necessary to teach third and fourth plane anesthesia. It is believed that curare has already assumed a permanent place as a supplement to anesthesia.

MARY KARP, MD

Holaday D. A.: Nitrous Oxide-Cyclopropane-Curare Anesthesia: A Review of 200 Cases. *Ann. Otolaryngol.* 1946 7 436

The recent advent of a purified, uniform extract of curare has provided the means by which an increasing number of anesthetists are obtaining relaxation during light general anesthesia. Curare acting peripherally paralyzes skeletal musculature progressively and quantitatively. Thus the differential paralysis of all somatic muscles save those necessary for respiration, may be procured. The mode of action is interference with the chemical transmission of impulses to the motor end organ, where such mechanism is cholinergic, and affects neither the normal conductivity of the nerve nor the contractility of the muscle fiber. In increasing dosage curare appears to affect the autonomic nervous system and probably the central nervous system. Unna and co-workers have observed that in vagotomized animals a bradycardia results from administration of betacrythroidine, a tertiary ammonium base closely related pharmacologically to curare. There is evidence that curare also affects the central nervous system. Puck and Unna think it is likely that this is the result of an interference with synaptic transmission within the central nervous system. Thus it is apparent that curare has no simple peripheral action but rather a multiplicity of effects on the nervous system. Curare was adopted by the author as an adjunct to anesthesia with the thought that it would more safely provide relaxation for long operations. A review of the first 200 cases in which it was used is

presented. About one-seventh of these patients were poor risks and more than one-third were only fair risks.

The first cases were conducted by a method similar to that described by Cullen. It shortly became apparent that second plane anesthesia was not necessary for fully curarized patients. Anesthesia was then induced with cyclopropane and later lightened with a mixture of nitrous oxide and cyclopropane. The postoperative course of these patients was improved in that they reacted sooner and showed less depression of blood pressure and pulse rate.

This technique was later modified to eliminate the induction with cyclopropane. Doses of from 10 to 30 mgm. of morphine sulfate and 0.5 to 1.0 gm. of hyoscine hydrobromide were given for premedication. Additional morphine sulfate was administered at approximately hourly intervals during the longer operations to maintain a basal narcosis. Anesthesia was induced with 85 to 90 per cent nitrous oxide and maintained in light first plane by a mixture of 60 to 70 per cent nitrous oxide and 1 to 2 per cent cyclopropane in oxygen, delivered into a semiclosed carbon dioxide absorbing system. Curarization was initiated with 40 to 60 units of curare at the time of incision of the skin.

The course of the patients in the operating room was satisfactory. Postoperatively however respiratory depression sufficient to require nasal oxygen and other supportive treatment was frequently encountered. Thereafter the initial dosage of morphine was reduced to from 10 to 20 mgm. with no additional dose being given except in a few cases in which the operation lasted more than two hours. Too little anesthesia with concurrent curarization however has its complications. Reflexes of sufficient strength to produce spasm of the muscles of respiration can be initiated by excessive stimulation in the operative field. Additional curare may correct this, but may also produce undesirable respiratory depression. A more satisfactory method for interrupting these reflexes is to deepen the plane of anesthesia. We found it expedient therefore, to insure adequate premedication with morphine and to increase the concentration of cyclopropane in the anesthetic mixture to from 5 to 8 per cent during the initial phases of the operation. Cyclopropane can usually be reduced to 1 or 2 per cent concentration as soon as the curarization has been completed and discontinued entirely after 60 to 90 minutes.

Curare and cyclopropane or nitrous oxide were used to supplement an inadequate spinal anesthesia. Curare was combined with sodium pentothal in 5 cases without the appearance of severe respiratory depression or any noticeable augmentation of the curare effect as has been reported. Either was the principal anesthetic agent in 3 cases in which curare was used. The experience of the author with these cases supports the conclusions of other writers that either potentiates strongly the action of curare. In 4 cases in which basal anesthesia was established with avertin, 20 per cent less curare was required to pro-

duce intercostal paralysis than for corresponding cases in which inhalation anesthesia was employed without avertin. Curare was administered intramuscularly in 7 cases. The full effect develops over a period of 15 to 20 minutes but the duration of effect is about 40 minutes. It must be emphasized that the rate of absorption of drugs administered intramuscularly is a function of the state of the circulation. If the blood flow should be impaired in any way while a significant amount of curare remains in the tissues subsequent improvement in the circulation may produce a dangerous degree of curarization at a time when the patient is not properly attended.

Various patients included in this study were selected because they were poor risks. These included some patients on whom a surgical procedure would not have been attempted except for the availability of an unusually favorable type of anesthetic. The average operating time was 119 minutes. The smallest intravenous total dose of curare was 20 units, the greatest total dose was 300 units. The average total dose was 152.7 units. The average initial dose was 74.65 units. Curare was usually given in divided doses over a period of 10 minutes starting with 40 or 60 units. Maintenance doses were 20 units given every 20 to 30 minutes.

Pulmonary complications were encountered post-operatively in 8 cases. Severe respiratory depression requiring intermittent compression of the rebreathing bag to assist ventilation occurred nine times in the series. In every case in which it was required, artificial ventilation by this method was adequate to carry the patient over the period of depression. In certain cases however especially those involving elderly arteriosclerotic individuals having a tendency toward hypertension, the blood pressure rose as much as 100 points during a period of apnea and returned to normal only after full, spontaneous respiration was resumed. This was interpreted as indicating first that the most skillfully applied artificial method for ventilation is not as efficient as the patient's own unimpeded respiratory movements and second, that curare apparently does not interfere with the normal compensatory mechanisms of the cardiovascular system for combating hypoxia. Five cases are presented in detail.

The type of anesthesia developed during this study by permitting the use of unusually light planes of anesthesia, may be employed to advantage for almost any type of operation. Its greatest bene-

fits, however lie in its use in long shock-inducing abdominal operations in which relaxation is a prerequisite, and in providing safe anesthesia for poor risk patients. It possesses few of the disadvantages inherent in other methods. The degree of success with which balanced nitrous oxide-curare may be used depends upon the skill of the anesthetist. The dangers associated with its use result from over curarization, or under anesthetization.

MARY FRANCES POE, M.D.

Sarnoff S. J., and Arrowood, J. G.: Differential Spinal Block. *Surgery* 1936 20 150.

Six patients were given light procaine solutions into the lumbar spaces by means of the continuous intraspinal method of Lemmon. Eight thermocouples were then placed as follows: 1 on the plantar aspect of each great toe, 1 on the lateral aspect of the dorsum of each foot, 1 each on the palmar aspect of the right thumb and middle finger and 2 in different parts of the room. The thermocouples were connected to a device which continuously recorded their temperatures. The initial dose of 10 c.c. of a 0.2 per cent solution of procaine hydrochloride was run in about 3 minutes. Thereafter 15 drops per minute were allowed to run in until the desired effect or height of block was attained.

Blood pressure, pulse and neurological observations were made at regular intervals. Neurological examination included the appreciation of pin prick, proprioceptive vibration, heat and cold sensation and motor activity. An increase of skin temperature from 24 C. to 31.5 C., or above, was assumed to have caused a complete block of the vasoconstrictor nerve fibers in that area.

It was concluded from these experiments that it was possible to introduce a concentration of procaine into the subarachnoid space which would block the fibers carrying vasoconstrictor impulses to the periphery and also those concerned with pin prick without materially affecting fibers concerned with touch, proprioception, vibratory sense, or motor power. This was termed differential spinal block. Hypotension was considered a result of the interruption of sympathetic vasoconstrictor fibers and not due to muscular flaccidity or diminished thoracic excursions. It was found also that the level of loss of sensation to skin prick only very approximately parallels the level of block of other kinds.

MARY KARP, M.D.

PHYSICOCHEMICAL METHODS IN SURGERY

ROENTGENOLOGY

Lofstrom, J. E., and Nurnberger, C. E.: Irradiation Sickness: Histamine Effect Treated with Benadryl. A Preliminary Report. *Am. J. Roentg.* 1946 56 211

The authors recommend the use of benadryl (beta-dimethylaminoethyl benzhydryl ether hydrochloride) for irradiation sickness. Eighteen cases of the relief of symptoms of anorexia, nausea, vomiting, weakness and headache by the use of benadryl. All of the cases were improved by this medication. The degree of relief varied from patient to patient.

Both oral and intravenous administration of benadryl were tried with the impression that oral administration will yield the desired amount of relief in most cases of irradiation sickness. The fundamental causes and mechanism of this condition are not known. The basis of this study and theoretical explanation of the results rests upon the contention that histaminelike bodies are developed in the blood of patients subjected to roentgen therapy and upon the hypothesis that benadryl neutralizes these substances by virtue of its antihistamine action. Elevated blood histamine was found in the 1 patient in this series of whom the blood was examined.

The conclusion the authors draw from the small series of cases is that the use of benadryl in the treatment of irradiation sickness is beneficial.

FRANK L. HOSSET, M.D.

Harper, R. A. K.: Some Observations on Roentgenography of the Pancreas. *Proc. R. Soc. M. Lond.* 1946 39 534

Roentgenography of the pancreas is of limited value at present and will remain so until excretory pancreatography is perfected. Since the diagnostic value of the symptomatology of pancreatic disease is disputable also roentgenological examination is given preference for diagnosis even in its present form.

Known methods of examination of the pancreas by x rays are Pneumoperitoneum (largely abandoned), gastric pneumography (largely abandoned), demonstration of opacities on abdominal films, barium studies of the stomach and the duodenum along its entire length for location of displacement, indentation, compression, invasion, and disturbance of the mucosal pattern, and barium studies of the small intestines for motility.

The conditions thus demonstrable are postinflammatory calcification of the pancreas, calcified pancreatic duct stones, pancreatic cysts, enlargement of the gland due to chronic pancreatitis, anomalous head of the pancreas surrounding the duodenum like an annular tumor, primary carcinoma of the pancreas, metastatic carcinoma, and lympho-

sarcoma, Hodgkin's disease, and retroperitoneal sarcoma involving the gland or stimulating pancreatic enlargement.

The differentiation between these conditions is rarely possible on a roentgenological basis. The differential diagnostic points are discussed.

GERHART S. SCHWARTZ, M.D.

Somerville, E. W.: Air Arthrography as an Aid in Diagnosis of Lesions of the Meniscus of the Knee Joint. *J. Bone Surg.* 1946, 28 451.

Many methods of visualization of the knee joint have been reported in the literature. In this series of 331 arthrograms, filtered air was used following 4 hours of skin preparation. The cassette was curved and mounted on a 6 inch stand. Routine views consist of 4 tangential views (round the clock views) of each meniscus. The medial or lateral joint was widened by holding the thigh firm and abducting or adducting the leg. McGaw and Weckesser (*J. Bone Surg.* 1945 27 432) devised a simple block frame for the same without subjecting the examiner to excessive irradiation.

The medial meniscus is adherent to the capsule and tibial collateral ligament, appearing in the anteroposterior film as a small triangular density surrounded by air. The size of the meniscus becomes larger in the tangential posterior views. The lateral meniscus is long and thin, extending from the capsule into the joint and it is raised from the tibia.

In the lateral posterior tangential view the meniscus becomes more triangular in shape. It may be continuous with the capsule or slightly separated by the popliteal tendon. The latter separation is not to be misinterpreted as a tear.

The bucket handle tear is found most frequently. The displaced fragment is seen usually in the lateral condylar notch. Peripheral tears of the lateral meniscus result in undue anterior or posterior mobility of the meniscus with a defect which may be wider than 3/8 inches. (The usual popliteal cyst defect is 3/8 inch wide.) Remnants of the posterior horn, a contused meniscus, tag and discoid meniscus, loose bone fragments and semimembranous tears can be visualized.

A series of 331 knee arthrograms is reported. Of this group 300 were reported as normal and 31 as positive for a meniscus lesion. In the second group 205 patients were operated upon and a lesion was found in 195. In 4 of the 20 cases misdiagnosed as lesions were found in 3 there were synovial tags and hypertrophied fat pads, in 1 there was a loose body. In another torn cruciate ligaments. The incidence of error was 4.5 per cent among 334 cases of knee pathology.

Although there are no contraindications to pancreatography it is not desirable in case of fluid in the joint. Arthrography is a useful adjunct to the clinical

dian in arriving at a correct diagnosis. Many excellent reproductions of meniscus lesions are illustrated in the text.

MAURICE D. SACHS, M.D.

Frimann Dahl J.: On the Value of Planigraphy in Bronchial Cancer. *Acta. radiol.*, Stockh. 1946 27 99.

Fifty-six cases of bronchial cancer were examined by means of planigraphy. In all cases satisfactory films were obtained. In 46 the planigraphic findings were positive. (This material does not include a number of cases with known bronchogenic carcinoma which were not planigraphed for various reasons.)

Survey films of these cases showed likewise, a pulmonary density in 46 instances. Direct, or air bronchography was successful in 10 cases, with positive findings in 6. Oil bronchography was performed in 12 cases. In the rest of the cases this procedure was deemed unnecessary and was omitted.

The author concludes that planigraphy is of great value in showing small cavities, bronchial narrowing, bronchial obstruction, endobronchial tumors, and peribronchial infiltration. It is the best method for differentiation between tumors which do not involve the bronchi and those which surround and involve the bronchial tubes, the latter almost always representing carcinomas.

The method is superior to bronchography with iodized oil because it does not require any preparation of the patient. It is harmless and fast and it is more often conclusive than the other procedures. For accurate localization, planigrams in 2 different projections should be obtained. It is planned to arrange for planigraphy in the erect position routinely for the demonstration of fluid levels. Thus far this has been done only occasionally as the present equipment for this position was too cumbersome for convenient operation and a moving grid was lacking.

GERHART S. SCHWARTZ, M.D.

Popp W. C., and Watkins, C. H.: Roentgen Therapy for Leucemia. *Med. Clin. N. America*, 1946 30 199.

In general in acute leucemia the disease is active and death may ensue in a few days to a few weeks. In chronic leucemia, the patient may live for from 2 to 4 years. In exceptional cases the process may be controlled for much longer periods. In the subacute forms the life expectancy will usually fall between these two extremes.

Roentgen treatment is as good a therapeutic measure in cases of leucemia as is known at the present time. Although the effect is entirely palliative, yet with properly supervised treatment a patient can be maintained in a useful capacity. Much disagreement is apparent between hematologists and

radiologists as to whether or not roentgen therapy prolongs life. The authors inferred that in some instances life seems to be prolonged considerably. Even this may not be wholly true, the fact that the general health of the individual patient is usually maintained at a better level with the use of roentgen treatment is sufficient to warrant its acceptance as a therapeutic measure in the treatment of leucemia. The close co-operation of the hematologist and the radiologist is important in the successful care of leucemia.

MISCELLANEOUS

Thorndike, A.: Rehabilitation of the Surgical Patient in Army Hospitals in World War II. *Am. J. Surg.* 1946 72 404.

During World War II the Medical Department of the Army developed an extensive reconditioning program primarily in an effort to return as many wounded men as possible directly to active duty in as short a time as possible, but also to return to limited service or useful civilian life those individuals who could not be completely salvaged. The program was planned for the surgical patient and developed in 3 aspects—physical, educational, and occupational. The success of the Army surgery plus the reconditioning program was gauged by the return of 58.8 per cent of the wounded to active duty within the overseas theaters, the best results being from the Convalescent Centers of the European theater where 84.5 per cent of the patients were returned to duty within the theater.

This article concerns itself chiefly with the physical reconditioning program. The rehabilitation plan was started early in convalescence, with classes of exercises adaptable progressively to those in bed, in the ambulant ward, and in the fully ambulant group. There were also special programs devised for special categories of the wounded, such as the amputees, the thoracic cases, the paraplegic, the deaf, and the blind. It was found that even very early after injury the afebrile patient profited by exercises which used the uninjured parts and later in convalescence remedial exercises and occupations adapted to the specific injury were initiated.

The author makes no attempt to detail the whole program, but outlines the exercises designed for the bed patient since they are the most useful in civilian hospital practice. He accompanies the outline with a series of very clear figure diagrams for each exercise, and recounts the muscles used in each. It is understood that few if any bed patients are able to do all the exercises the prescription in each case. In Army practice being left to the discretion of the ward surgeon.

MISCELLANEOUS

CLINICAL ENTITIES—GENERAL PHYSIOLOGICAL CONDITIONS

Forgas, J., Kornegay G B., and Henley T F :
Studies on Streptomycin Assay in Body Fluids.
J Lab Clin M 1946 31 514

Various methods of assaying antibiotics are mostly modifications of the cylinder-plate method.

A method is described for assaying streptomycin in body fluids, particularly in the blood and in the urine. The method was developed in order to clarify absorption, excretion, and activity of the drug in human beings.

The amount of streptomycin is estimated from the width of the zone of inhibition observed on an agar plate seeded with a special strain of *Bacillus subtilis*.

ARTHUR J LESSER, M.D.

Kornegay G B., Forgas, J., and Henley T F :
Studies on Streptomycin. Blood Levels and Urinary Excretion in Man and Animals. *J Lab Clin M* 1946 3 533

Streptomycin was administered to mice, guinea pigs, rabbits, and human beings by intravenous, subcutaneous, intramuscular and intraperitoneal injections, and maximum blood levels appeared from 15 to 60 minutes following injection.

An intramuscular dose of 30,000 units given to human beings every 3 hours resulted in blood levels from 1 to 2.5 units per cubic centimeter. Higher levels can be obtained by increasing the dose.

No changes in red or white count were found following the administration of streptomycin. Variations of the blood levels from a given dose were observed from animal to animal and in the same experimental animal from day to day. Similar irregularities were observed in human beings. In man a considerable daily variation of urinary streptomycin excretion was observed, and a prolonged urinary excretion after cessation of streptomycin therapy was considered evidence of storage somewhere in the body.

No satisfactory vehicle for oral administration was found and the absorption of streptomycin from the gastrointestinal tract was not followed by therapeutic blood level.

ARTHUR J LESSER, M.D.

Oberrio, J M : Acroparesthesia (Acroparestesia. La artritis de hombre el plexo braquial y la acroparestesia de miembro superior). *Rev Is mid argen* 1946, 60 557

There are three clinical forms of acroparesthesia, namely acroparesthesia diurna, acroparesthesia nocturnal and mixed acroparesthesia. Associated disturbances are vasomotor, motor and trophic, and also sensory disturbances.

In all of the cases seen by the author since 1915 the acroparesthesia coexisted with an arthritis of the

shoulder while the changes of simple acroparesthesia which is a sensory disturbance, are of the brachial plexitis. The scapulohumeral arthritis originates from a neuritis of the circumflex and suprascapular nerves. In the nocturnal syndrome, the symptoms originate after arising from an auto-intoxication originating during sleep. In night this auto-intoxication is neutralized but on arising there is an increased basal metabolism and a decreased carbon dioxide concentration in the blood due to increased pulmonary ventilation and therefore intoxication is aggravated.

ARTHUR F CIRIELLO, M.D.

McLaren J W : Calcium Gluconate Injection in Muscle. *Brit. J Radiol.*, 1946, 19 314

It would appear that the injection of calcium gluconate carries with it some risk of damage to muscle tissue which may be of a serious nature. It is, however, difficult to ascertain the factor which causes the calcium deposition, since this happens must be of infrequent occurrence. Certain solutions of calcium gluconate may be unstable and therefore more likely to be precipitated, and it is suggested that a myositis may be set up as the crystals of the gluconate are of the sharp needle type. It is also known that calcium salts are nonlipid-soluble and are only absorbed with difficulty from a deposit there, so that the injection should be made only into muscle and care taken that fatty tissue is not entered at the injection site by the needle. Experimental injection of calcium gluconate into rabbits has not produced any demonstrable calcification in muscle. The view recorded by Lamm shows that serious results can be brought about by injections of calcium gluconate, and though it would appear that absorption of the calcium usually occurs there may be permanent damage which in some instances may be of an extensive nature.

The author reports another case of calcification in muscle shown in roentgenogram.

Abbott W E., Hirschfeld J W., Williams, H H., Pilling, M A., and Meyer F L : Metabolic Alterations following Thermal Burns. The Effect of Altering the Nitrogen and Caloric Intake of Administering Testosterone Propionate on the Nitrogen Balance. *Surgery* 1946, 20 1

Previous studies indicate that both experimental animals and human beings show a characteristic metabolic response after thermal injuries. This reaction consists of a marked negative nitrogen balance, temporary elevation of the blood sugar, amino acid concentrations, salt retention, increased water intake and output with actual water retention, and temporary increase in urinary excretion of ketosteroids and cortin.

In this article the authors report the effect on the nitrogen balance of altering the food intake or of administering a nitrogen retaining hormone (testosterone propionate) in 45 burned patients and a group of animals with standardized experimental burns.

In moderate and severely burned patients the nitrogen deficit is more marked than in those with a smaller burn and attempts at forced feeding of patients who show the greatest loss meet with the most difficulty. Consequently a diet containing 1.6 times the basal caloric requirement (20 per cent protein) was started on the third day after the burn and was well tolerated by most patients. Such a diet kept nitrogen loss at a minimum and there was an earlier return to a positive nitrogen balance than in those patients receiving a lower caloric and protein intake. There was no evidence in a study of these patients that raising the carbohydrate content of the diet caused any significant sparing of nitrogen nor was there any substantial effect noted from the addition to the diet of DL methionine (in an amount equal to 1 per cent of the diet).

The severity of the nitrogen deficit bears a direct relation to the extent and severity of the surface area injured and is also dependent upon sex, age, nutritional state, fever, infection and type of therapy. High diets (from 3,000 to 5,000 calories containing from 100 to 300 gm. of protein) are probably deleterious during the catabolic stage following a burn and should not be given during the first week or two.

Eight burned patients were given testosterone propionate (25 mgm. daily for 10 days) without conclusive results as to the value of such therapy. This hormone reduces the loss of urinary nitrogen. It should not be used as a substitute for food but used in an attempt to conserve and utilize better the maximum diet which the patient can tolerate. Androgenic therapy must be employed cautiously as it may produce masculine characteristics in women. It also causes water and salt retention hence it is preferable to delay instituting therapy until the catabolic phase has subsided (from 8 to 14 days).

Cammermeyer, J. Tumor of Tactile End Organ.
Arch. Path. Chic., 1946 42: 1

The author reports the case of a 50 year old man who had a congenital tumor on the mediovascular side of the two distal phalanges of the left index finger which had grown some during the 2 or 3 years preceding its removal. There had been no pain nor other disturbance except that due to the mere presence of the tumor. It was removed by excision together with an exostosis and healing was smooth.

On microscopic examination the tumor was found to consist of masses of fibrous connective tissue which surrounded conglomerates of tactile end organs.

The article is complete with photomicrographs, schematic drawings, and detailed discussions of the histologic structure of this tumor.

The author reviews the literature relating to similar structures and concludes that his case is unique in several aspects. *HEINRICH LAMM, M.D.*

Jones, G. E., S. Delfs E. and Foote E. C.: The Effect of Thioracil Hypothyroidism on Reproduction in the Rat. *Endocrinology* 1946 38: 337

The authors experiments were planned in an effort to demonstrate what specific effect hypothyroidism might exert on the ability of rats to reproduce. The hypothyroidism was produced with thioracil because of the difficulty in producing this state surgically in rats.

Fourteen male rats were given approximately 25 mgm. of thioracil daily by placing the drug in their drinking water and then certain groups were mated after having been fed thioracil over periods of 49, 166, 204, and 259 days. Three of the animals were obviously ill from other causes and when they were ruled out 10 of the remaining 11 sired the litters. Each rat was mated only a single time with a single female.

There was a tendency toward unsuccessful mating following the one hundred and sixty-sixth day of thioracil administration which probably reflected the toxicity of the drug rather than any impairment of reproductive capacities.

The results of these experiments on male rats indicate that hypothyroidism as induced by thioracil has no effect upon the reproductive system of the male rat as judged by the ability to sire normal litters.

Thioracil was then fed in the same manner to 15 female adult rats. The dose was calculated to be 20 mgm. daily. There were 27 matings, 22 of which resulted in resorptions. The 5 litters occurred in the first group of matings made 81 days after the beginning of thioracil administration, the remaining 4 matings of this group terminated in resorptions, as did all 18 matings made after the one hundred and twenty-sixth day of thioracil administration. One interpretation of the findings may be that the matings of the first group reflect a state of borderline hypothyroidism perhaps comparable to the period of about 3 months described by Engle which is necessary to dissipate the effect of thyroid feeding in previously thyroidectomized monkeys. Following the time lapse which may be necessary pregnancy will occur but terminates in resorption in 100 per cent of the cases.

Experiments are now being done in which rats are given thioracil thyroid extract in order to determine whether the hypothyroidism or the thioracil causes this effect.

Hypothyroidism induced by thioracil has no effect upon the reproductive system of the adult male rat as judged by the ability to sire litters. Prolonged thioracil administration associated with hypothyroidism in the adult female rat does not cause sterility but interferes with continuation of

gestation as it leads to the resorption of embryos in 100 per cent of the cases. If the drug is given over a period of less than 100 days some rats may deliver litters which are normal in growth and development and reproduce normally.

Huggins, C., and Russell, P. S.: Quantitative Effects of Hypophysectomy on Testes and Prostate of Dogs. *Laboratory* 1946 39.

Some of the chemical changes occurring after hypophysectomy in the prostate and testes of dogs are described in this paper. For several reasons, it has become important to study the involution of normal tissues, particularly since the methods which induce regression in them can sometimes be applied to produce dysfunction in neoplastic cells. The endocrine glands, as implied by definition, exert remote control of certain other tissues.

Previous investigations have been directed toward weight and cytology changes and tissue metabolism of the testis after hypophyseal extirpation. The present study deals with quantitative effects produced on the testes and prostate.

Hypophysectomy was done on 4 dogs by the method of Dandy and Reichert under intravenous sodium seconal. The testes were measured through the scrotum preoperatively with a caliper and dogs with testes of identical size on each side were selected. Hypophyseal removal was judged complete in these animals since no fragments of the sella were found at necropsy and the characteristic regressive changes were found in the adrenals. At the time of hypophysectomy one testis was removed for chemical study and the opposite one was removed when the dogs were sacrificed from 41 to 63 days postoperatively.

In 3 additional dogs, removal of the hypophysis was adjudged incomplete since minute fragments of tissue identified histologically as pituitary were found at necropsy.

In 3 normal dogs a wedge-shaped section of the left lobe of the prostate was removed for phosphatase determination and the testes were then removed. The right lobe of the prostate was assayed at necropsy 3 months later.

All testes were weighed and the content of water, fat, and chloride determined. The acid and alkaline phosphatase content was determined in the hypophysectomized and castrated dogs as well as in 9 normal adult dogs and 3 immature puppies.

In conclusion the authors state that complete hypophysectomy produces slight increase in body weight.

After hypophysectomy the testicular weight increases to two-thirds the normal value and is associated with decreased water and increased chloride and fat concentration. The total fat is reduced. There is a dissociation between form and function in the Leydig cells, form and fat content being rather well retained while androgen production is greatly reduced or lost. Spermatogonia persist in the testes being found in a single layer in the tubules.

Total hypophysectomy produces profound atrophy of the prostatic epithelium which is reduced to the prepubertal state. Prostatic acid phosphatase is decreased below the castrate level to values comparable with those found in juvenile animals. Alkaline phosphatase is decreased to prepubertal level after hypophysectomy but is remarkably elevated after castration.

Subtotal hypophysectomy in dogs is associated with prostatic atrophy but with retention of normal spermatogenesis.

EDMUND R. DOUGHERT, M.D.

gestation as it leads to the resorption of embryos in 100 per cent of the cases. If the drug is given over a period of less than 100 days, some rats may deliver litters which are normal in growth and development and reproduce normally.

A NEW TECHNIQUE FOR PULMONARY SEGMENTAL RESECTION

Its Application in the Treatment of Bronchiectasis

RICHARD H. OVERHOLT, M.D., Boston, Massachusetts and LAZARO LANGER, M.D.,
Cordoba, Argentina

DOCTORS are confronted with few problems that are more serious than those presented by a patient suffering from bronchiectasis. The disease process, if untreated, is irreversible, progressive, and for most patients eventually causes death. On the other hand, of all chronic pulmonary diseases, bronchiectasis is one of the most hopeful for the reason that pulmonary resection affords not only alleviation of symptoms, but also cure in a high percentage of cases.

Although the fundamental pathology of primary bronchiectasis has been known for decades, only in recent years has the characteristic distribution of the disease in bronchopulmonary segments been realized. The increasing use of bronchography and the detailed study of surgical specimens have shown that bronchiectasis is primarily a segmental disease and rarely involves an entire lobe. In addition, bronchiectasis tends to involve the bronchopulmonary segments in certain patterns. Basal segments of the lower lobes are most commonly involved. The lingula division of the left upper lobe and the bronchi of the right middle lobe are frequently found to be diseased along with the basal segments. The superior segment of the lower lobe, how-

ever, is rarely affected. Another very important pathological and clinical observation has been that the distribution of primary bronchiectasis, as far as the affected segments are concerned, has usually reached its full extent at the time of diagnosis. Any progression of pulmonary involvement from this point on will not be through involvement of other segments by the bronchiectatic process, but by associated suppurative changes in the pulmonary parenchyma itself.

In recent years, many excellent anatomical studies (2, 3, 4, 6) along with increased surgical experience in resecting pulmonary tissue, have demonstrated that the bronchopulmonary segment is a surgical unit and lends itself to removal without undue technical difficulties or risk. As a result, segmental resection is now being used by us with increased frequency in the surgical treatment of bronchiectasis. Segmental resection not only eradicates all of the diseased segments, but it also eliminates the necessity of a sacrifice of uninvolved segments. This approach to the problem permits the accomplishment of two fundamental principles of surgery: (1) cure of the patient; (2) the preservation of as much functional tissue as possible.

During the past year, we have developed a surgical technique which facilitates the removal of any bronchopulmonary segment. The use of clamps on lung tissue has been elim-

From the New England Deaconess Hospital and Tufts College Medical School, Dr. Overholt, Clinical Professor of Surgery; Dr. Langer, Fellow in Surgery, Tufts College Medical School.

inated. Damage to healthy segments is avoided. The intersegmental plane is dissected so as to ensure removal of all diseased bronchi.

The purpose of this paper is to describe an original and new technique of segmental resection. We wish to refer to its application in 23 cases of bronchiectasis.¹

IMPORTANCE OF SEGMENTAL RESECTION

Bronchiectasis is primarily a segmental disease and frequently bilateral. It usually involves certain bronchopulmonary segments within the lobe rather than an entire lobe. Unsegmental disease is found less frequently than unilateral multiple segmental disease. It is also less common than bilateral involvement. In the last one hundred consecutive cases of primary bronchiectasis studied by us 85 per cent were multiple segmental and in 30 per cent the disease was bilateral. In our series, the lower division of the left upper lobe (lingula) was involved in about 60 per cent of those patients whose principal disease was in the left basal segments. On the right side the middle lobe was found to be involved with the right basal segments in 45 per cent of our cases. A frequent bilateral pattern to be found shows involvement of the right middle, the lower divisions of the left upper (lingula) and both right and left basal segments.

Clinical observations have shown that the severity of symptoms is closely related to the amount of tissue damaged. Experience also has demonstrated that good end results parallel the surgeon's ability to eradicate all portions of lung that are diseased. If entire lobes are considered as surgical units, serious respiratory embarrassment will result if the disease is completely removed in bilateral cases; for example, the removal of the right middle lobe, both lower lobes, and lower divisions of the left upper lobe leaves the patient with one complete and one partial lobe which may not be sufficient for anything more than an invalid existence.

¹Segmental resection is also being used for other localized conditions. Up to the present time this technique of segmental resection has been carried out in chronic lung abscesses (4 cases), hamartomas (1 case), metastatic embryocarcinoma (1 case), and pulmonary tuberculosis (4 cases). The individual resection of the posterior and apical segments of the upper lobe, the superior of the lower, the posterior basal of the lower and the anterior of the upper were involved.

BRONCHIAL NOMENCLATURE

Bronchial nomenclature is far from being standardized. Various names for the bronchopulmonary segments have been suggested. This lack of standardization has led to much confusion. Jackson and Huber² emphasized the need for terminology which will be acceptable to the bronchoscopist, the thoracic surgeon, and the radiologist and which will meet the approval of the anatomist. They have proposed a nomenclature now widely accepted which has been used herein (Fig. 1).

PRACTICAL CONSIDERATIONS

The conception that a bronchopulmonary segment be considered as a surgical unit is gaining greater acceptance. Nelson called attention to the pathological significance of certain segments and called the lingula the left middle lobe (counterpart of the right middle). He subdivided the lower lobe into two principal divisions, the dorsal (superior), and basal. He found that, anatomically, each segment possesses independent bronchovascular structures and is separated from the adjacent pulmonary tissue by an avascular plane. From time to time thoracic surgeons have found it necessary to remove a part of a lobe by the use of clamps and multiple sutures. Most frequently this technique was practiced in treating left lower lobe bronchiectasis with involvement of the lingula. The indurated lower tip of the upper lobe would be excised without precise dissection. Churchill and Belsey and Blades (7) have called attention to the importance of the removal of the lingula and other segments in the treatment of bronchiectasis and other diseases.³

Boyden has pointed out that from a practical standpoint, most of the segments can be considered to be surgical units, but not strictly bronchovascular units. He found some arteries mainly in the upper lobes, to be intersegmental and the veins to drain blood from adjacent segments.

²As common basis for the choice of names, they have taken the position of the segment on the lobe. Terms like apical, basal, and lingula are unanimously recognized as part of the lung; anterior and posterior, superior and inferior, and medial and lateral indicate the position of the segments within the lobe.

³Since this manuscript was submitted for publication, Church and Dretter in *Journal of Thoracic Surgery*, 1940, 5: 277-284, have discussed the importance of lingulectomy in bronchiectasis and describe a technique for its removal.

Fig. 2 Anatomical drawing of the left pulmonary artery with all of its branches as seen in the interlobar approach with both lobes retracted.

Not infrequently the presence of a rudimentary fissure or crevice will indicate the topographical boundary of a bronchopulmonary segment. Surface markings suggesting rudimentary fissures become more evident after the lung has been collapsed. The involved segments may be contracted or already completely collapsed. There may be a difference in pigmentation. The diseased segment some times fails to deflate as rapidly as the normal segments and variations in intrapulmonic pressure by inflating and deflating the lung will also aid in identification.

Accurate delineation of the bronchopulmonary segments is accomplished by (1) deflation of the lobe (2) temporary occlusion of the bronchus (3) reinflation of the lobe by means of increased positive intratracheal pressure.

RELATED ANATOMY OF THE SEGMENTS

A thorough knowledge of the intrahilar and related segmental anatomy of the lung is indispensable if one is to apply the surgical principles of individual treatment of anatomical

structures in partial lobectomy. The anatomical pattern may vary and an anomalous distribution of bronchovascular structures may be found. These anomalies can be recognized and do not interfere with the treatment of the segment as a surgical unit.

The pathological significance of certain segments selectively involved by bronchiectasis has already been referred to. The frequency in which bronchiectasis is found in both basal segments and in the lower division of the left upper makes these particular segments of great practical importance.¹

Basal segments—right and left side In normal lungs each basal group constitutes approximately two thirds of the lower lobe. In bronchiectasis this proportion changes as contraction of basal segments occurs and the superior segment hypertrophies or enlarges. In longstanding disease starting in childhood the superior segment has been found to approach in size the normal lower lobe. The hilar arrangements on both sides are similar.

Related anatomy of only the most important segments involved in bronchiectasis has been given.

Fig 3. Anatomical drawing of the right pulmonary artery and its branches as seen in the interlobar approach with the lobes retracted. Insert shows the pulmonary artery as seen anteriorly. The middle lobe has been retracted medially.

The inferior pulmonary vein is an anterior structure in the pulmonary root but its tributaries emerge from the lobe in a plane posterior and inferior to the bronchus. Several tributaries from the lower lobes form the inferior pulmonary vein. They frequently are found to be four. One is from the superior segment, and the remaining three are from the basal segment. The branch from the superior segment lies posterior to the basal bronchus which it crosses and should be identified and preserved when basal segmental lobectomy is performed. This vein may be as large as the combined basal veins.

The bronchus to the lower lobe has two major segmental divisions: the superior and the basal. The first division of the lower lobe bronchus is the branch to the superior segment. It arises both right and left, from the posterolateral aspect of the main bronchus. On the left side it arises below the level of the upper lobe bronchus and on the right side it arises at the beginning of the lower lobe bronchus about the level of the middle lobe bronchus. The bronchi in the basal segments are, in reality, the continuation of the main bron-

chi. Between the superior division of the bronchus and the subdivisions of the basal segmental bronchi there is a common stem from 1 to 1.5 centimeters in length which is suitable for individual ligation.

The arterial distribution of the lower lobe parallels, to a certain extent, the bronchial structures of it. The pulmonary artery on the left side (Fig 2) during its course deep in the interlobar fissure gives off branches to supply the segments. The highest artery to the lower lobe is the superior segmental branch. Its level or origin is opposite to the branch of the lingula and sometimes higher. On the right side (Fig 3) this branch arises from the posterolateral aspect of the interlobar portion of the pulmonary artery opposite the level or slightly above the origin of the middle lobe artery or arteries. The basal segmental arteries (four on the right and three on the left) follow their respective bronchi. Their common stem which constitutes the prolongation of the main pulmonary artery is sometimes too short to allow its ligation in mass and for this reason each branch should be disposed of separately.

Fig. 4

Fig. 5

Fig. 6

Fig. 7

Lower division of the left upper lobe (lingula)

The vein from the lingula division is a tributary to the superior pulmonary vein and enters it at its lowest point. It lies anterior and inferior to the bronchus and is formed by two branches the superior and the inferior, lingula veins. They are best approached from the anterior aspect of the hilum.

The lower, or lingula divisional bronchus branches from the inferior aspect of the left upper lobe bronchus and its single trunk is divided into two segmental bronchi the superior and the inferior. The inferior bronchus descends to the tongue of tissue in the antero-inferior angle of the upper lobe.

The artery to the lingula is a branch of the pulmonary artery and it takes origin from the main trunk deep in the interlobar fissure (Fig 2). Its course is posterior and lateral to the bronchus. Many variations in the lingula artery can be found. It may originate from a common trunk with the anterior segmental artery, or the two lingula branches may arise separately from the main pulmonary trunk.

TECHNICAL CONSIDERATIONS

Objection to clamp and suture method. In the past, segmental lobectomies or partial excision

Fig 4. 1 Left pulmonary artery; 2 anterior artery; 3, superior artery; 4, lingula artery; 5, basal artery; B, superior bronchus; C, basal bronchus. The fissure has been developed and the left upper and lower lobes are exposed. The basal segment is *slacked* and appears contracted and dark bluish in color. The superior segment is larger than average and has normal color. The pulmonary artery is situated deep in the interlobar fissure. It is anterolateral to the bronchus. The basal artery is exposed and the superior lingula and anterior segmental arteries are seen through the visceral pleura which has been partially dissected away. The first step after exposure of the pulmonary artery is the ligation of the basal branch. If the common stem of this artery is short, the various branches can be ligated separately to provide more room between proximal and distal ties. The insert shows the basal artery already divided.

Fig 5. 1 Left pulmonary artery; 3, superior artery; 4, left main bronchus; B superior bronchus; C basal bronchus; 6 inferior pulmonary vein; 7 superior vein; 8 basal vein. The lung has dropped forward exposing the posterior hilum. The pulmonary ligament has been divided. The inferior pulmonary vein lies anterior to the main bronchus, but its tributaries emerge from the lobe posterior to the segmental bronchi. Before the basal veins are ligated the superior segmental vein should be identified. It can be seen posterior to the basal bronchus and crossing over it. Insert shows the basal veins ligated.

Fig 6. A Left main bronchus B superior bronchus C basal bronchus 6 inferior pulmonary vein; 7 superior vein. The insert shows the basal bronchus partially divided

of pulmonary tissue have been accomplished by cutting through thick vascular pulmonary tissue between clamps and placing either a running suture ligature or individual ligatures in the lung substance held by the clamps. Distinct disadvantages of this practice should be mentioned.

1. It is impossible to place the clamps precisely in the intersegmental plane. Either too much or too little tissue is resected.

2. The application of clamps across the lung is rather crude and traumatizing. Bleeding and hematoma formation may be unavoidable.

3. Excessive suture material is necessary. This increases foreign body reaction and predisposes to secondary infection.

4. Puckering and reduction in size of remaining segments are produced. Re-expansion may tear the sutured lung surface.

Our method. During the past year we have developed a method of segmental dissection which is fundamentally sound.

The segment is held within the lobe by four principal structures the bronchus, the pulmonary artery vein and visceral pleura. All of these structures can be identified and divided prior to the dissection of the intersegment

and the superior vein retracted. The main drawing shows the stump of the segmental bronchus closed. Tacking forceps hold the bronchus, vein, and artery of the segment. While the bronchus is being amputated the operative field should be protected with gauze pads in order to avoid spillage of purulent material. The suction tip is constantly maintained close to the amputation line. The lobe has been inflated by oxygen under pressure. The demarcation line between the segments is now evident. The visceral pleura at this boundary is incised. After the pleura is completely free, the direction of the intersegmental plane begins in a retrograde manner.

Fig 7. 4 Left main bronchus B superior bronchus C basal bronchus 6 inferior pulmonary vein; 7, superior vein. The insert shows finger method of separation. The surgeon's thumb is applied directly over the bronchi and all the branches are "peeled off." This simple procedure is very useful because the fingers find the path of least resistance which is the intersegmental plane. A few connective tissue fibers may have to be divided with a knife or scissors. In the main drawing, an intersegmental vein can be seen on the raw surface of the lobe. A few communicating vessels have been ligated. Air bubbles can be seen leaking out from the lung. They do not constitute a problem because the airtight seal off spontaneously by the time the chest is ready to be closed. After the segmental lobectomy has been completed, all remaining bleeding points in the lung surface are sutured. If bronchial leaks are still present, they are repaired with interrupted sutures. Note the size of the remaining superior segment which represents a significant salvage.

Fig. 8.

Fig. 9.

Fig. 8. Pulmonary artery: 2 anterior artery; 3 superior artery; 4 lingula artery; 5 superior bronchus; 6 lingula bronchus. The remaining superior segment is retracted upward and the base of the fissure is exposed. The lingula artery has been prepared for ligation. Note that the lingula artery comes off from a slightly lower level than the artery to the superior segment. Both branches of the lingula artery have been tied distally and separately. The right angle clamp shown is used to dissect the artery. Proximally the artery is going to be tied with a main ligature of fine silk and a transfixion ligature. Insert shows the lingula artery divided. The lingula bronchus lies anteriorly to the artery. Its membranous portion can now be seen.

Fig. 9. Pulmonary artery: 6 lingula bronchus, 7 superior pulmonary vein, 8 lingula vein. The upper lobe has been freed from the pericardium and is held up. The superior pulmonary vein is exposed. The tributaries from the upper lobe pulmonary segments can be seen. Superior and posterior to the superior pulmonary vein lies the main pulmonary artery. The mediastinal pleura has been opened and the lingula veins dissected. The ligatures are placed distally on the two branches. The cartilaginous portion of the lingula bronchus can be seen superior and posterior to the corresponding vein. Insert shows the lingula vein divided and the corresponding bronchus more clearly exposed.

tal plane then the development of this plane is simplified and made possible. The bronchi do not traverse this plane. For practical purposes, this plane is avascular. The supporting framework of connective tissue is loose, slightly elastic, and yields to gentle blunt, and sharp dissection. Air leak of raw surface is negligible and self-sealing. Prompt healing of the denuded lung surface follows, as in other organs, since its blood supply has not been jeopardized, or the tissue traumatized.

The technique as applied to any segment is briefly as follows:

1. Identify and divide the segmental pulmonary artery. In all segments except the apical posterior (left) and the apical and anterior (right) the major fissure should be developed in such a manner as to find the segmental artery.

2. Identify and divide the segmental vein

3. Identify and divide the segmental bronchus.

4. Determine the line of demarcation between segments by inflation and incision of visceral pleura completely around the lobe at this line.

5. Start development of intersegmental plane at the secondary hilum. Holding forceps makes traction on the bronchus, artery and veins. Clamps on the lung tissue are not used and should be avoided as they may include ramifications of the bronchi. Dissection is done bluntly at first. Fibrous strands may be cut with scissors. Bronchi strip out between forefinger and thumb. The correct plane of cleavage is the one showing least resistance. One to six intersegmental vessels may have to be ligated. Mosquito hemostats are used. If there is a question of identifying a fine bronchus or a vessel, it is first cut and then ligated.

Fig. 10

Fig. 11

Fig. 10. 1, Pulmonary artery, 2, anterior artery, 3, superior artery. B, superior bronchus. D, lingula bronchus. The bronchus to the lingula segment can be seen closed proximally with two mattress sutures. Both of its branches have been tied distally. Note the difference in the appearance of the lingula and the remaining portion of the upper lobe. Insert shows the bronchus being cut.

Fig. 11. 1, Pulmonary artery, 2, anterior artery, C, basal bronchus, D, lingula bronchus. Insert shows the free pleural flap held in place with an Allis forceps and sutured with two wire sutures. The main drawing shows the lobes re-expanded with oxygen under positive pressure. Note the size of the superior segment which has been conserved. The lingula segment is very small and contracted and the remaining segments in the upper lobe represent about 7/10 of that lobe. The lingula is in the process of being removed in the same fashion as the basal segment.

Fig. 12.

Fig. 13.

Fig. 13. Healthy segments conserved after bilobar segmental resection also from a photograph.

if it bleeds. If it happens to be a bronchus the end is picked up again and it is stripped out to its termination. Much of the dissection can be accomplished with the thumb and forefinger. It has been surprising to us to find that

the structural attachment of the segment to the remaining portion of the lobe is so frail after the four supporting structures have been released. This completes segmental separation and treatment of the raw surfaces of the re-

Fig. 14. Roentgenogram at left show bronchiectasi in the middle lobe and anterior segment of the upper lobe on the right side and basal and lingula segments on the left

side. Roentgenogram on right, 2 months after resectal operation. Arrows indicate stumps of resected segmental bronchi

maining segment. No attempt is made to fold over edges or use grafts.

6. Reamputation and meticulous closure of the segmental bronchus is then carried out. We prefer to use two interrupted mattress sutures and two or three end sutures applied over a free graft of parietal pleura. Stainless steel wire (No. 35) or silk is used.

The resection technique of those segments most frequently removed for bronchiectasis is illustrated. The same principles may be applied to other segments (see Figs. 4 to 11). The patient is in the face-down position¹ and the head of the table is to the left. In all color drawings the artery is shown in red and the vein in blue.

During the past year and one-half we have adopted the face-down position with the diseased side dependent for pulmonary resection (5). The conventional side position places the diseased lung above the healthy lung and favors spillage of secretions and debris via the intercommunicating bronchi during the operation. The face-down position minimizes this danger. It also permits wider range of respiratory movement. Patients tolerate an open pneumothorax better and positive pressure is rarely required.

After completion of the operation the pleural cavity is thoroughly washed out with saline warmed to body temperature. The thoracic cage is reconstructed by two pericostal chromic catgut No. 2 sutures placed subperiosteally. The intercostal nerves should be carefully avoided. Postoperative pain is greatly diminished by these precautions. The intercostal muscles are loosely sutured with interrupted sutures. The muscles are closed in two layers with interrupted sutures. The superficial fascia is closed separately and the skin is sutured with a multiple needle technique. Silk (No. 9) is used throughout. Before the chest is closed a rubber catheter (No. 26) with lateral openings is placed in the pleural space and carried out through the lower end of the incision. Gentle suction is used for 24 to 48 hours.

POSTOPERATIVE ATTENTION

In the care of patients following segmental resection the same measures should be used

Fig. 15. Photograph of the patient, L. B. Front and back view 2 months following second operation

that have been found to be of value after routine lobectomy. The two primary concerns are maintenance of airways and complete re-expansion of the remaining segments. Oxygen therapy is rarely needed. Deeper breathing is more apt to occur if the patients are in a normal atmosphere. Patients should be stimulated to cough and raise. Undue postoperative pain seriously interferes with expectoration. Early changes in position are encouraged. The lower half of the chest should be temporarily immobilized by exerting pressure with the hands on the side operated upon because it allows cough and expectoration without discomfort. Bilateral bronchiectasis presents a particular problem after the operation on the first side because of the presence of secretions originating in the contralateral lung. Any accumulation of secretion should be avoided. Tracheal aspirations after insertion of a catheter via the nose will frequently suffice. The temporary catheter drainage is removed in 24 to 48 hours. Further evidence of fluid and air in the pleural cavity calls for aspiration by needle. Regular examination under the fluoroscope helps greatly in keeping track of the progress of re-expansion.

SUMMARY OF CASES

Twenty three segmental resections have been performed upon 21 patients for primary bronchiectasis. No deaths have occurred in this series and all of the patients have benefited greatly from the surgical intervention. All of the unilateral cases are free of symptoms. The age of the patients ranged from 7 to 56 years. Most of the patients were in the second or third decades. The duration of the disease was from 4 months to 27 years. The amount of sputum varied from 1 ounce to 20 ounces daily. The outstanding clinical features in the order of severity were as follows: repeated colds, bouts of pneumonitis, hemoptysis, cough and expectoration of purulent secretions. Foul sputum was present in 40 per cent of the cases. Bilateral lesions were present in 11 cases (52.4 per cent) with the following segmental distributions. In 10 cases the middle lobe, right basal and lingula and left basal segments were involved. 1 patient had the middle lobe, the anterior segment of the right upper and the lingula and left basal diseased. In the unilateral group 5 patients showed involvement of two segments. The lingula and left basal were involved in 3 cases, and the

TABLE I.—SUMMARY OF 21 CASES (23 OPERATIONS) AS TO AGE, DURATION OF DISEASE, AMOUNT OF EXPECTORATION SEGMENTS INVOLVED SEGMENTS REMOVED POSTOPERATIVE COMPLICATIONS AND PRESENT CLINICAL STATUS.

Case No. Name Age	Duration of Illness	Segments involved	Amount of apertures (ounces)	Segments removed	Date of operation	Complications	Present clinical status

J. M. 10	1 yrs	Middle and right basal (lingula and left basal)	0 ozs	Lingula and left basal	6-21-46	—	Too recent to evaluate

middle lobe and right basal segment were involved in the other 2 patients. The remaining 5 patients had their disease localized to only one segment as follows. Two were in the right basal, 2 in the left basal, 1 had the superior segment of the left lower lobe involved.

Bilateral bisegmental operations were performed in 2 cases. 1 in a 7 year old girl. During the first stage the middle and right basal segments were removed. Four months later the lingula and left basal segments were resected. The other patient was a 19 year old female who had a history of 15 years of cough and purulent sputum. During the first operation the middle and the anterior segment of the right upper were resected. Nine months later the lingula and left basal segments were operated upon. Both patients made an uneventful recovery following the operation and are free of symptoms.

COMPLICATIONS

In 4 cases bronchoscopy was necessary to aid in re-expansion. In each instance watery secretions were found but no definite bronchial plug. Bronchoscopy also revealed submucosal edema of the orifice of the segment adjacent to the amputated one. We believe that this pathological finding explains the obstructive atelectasis in the absence of a bronchial plug. In times past when all diseased segments were not removed thick tenacious sputum was a frequent postoperative finding. Following bronchoscopy all of the patients conditions improved and re-expansion was obtained. Empyema developed in 4 cases. One was treated locally with pleural aspiration and penicillin and cleared up entirely. The remaining 3 were drained. Bronchopleural fistula was demonstrated in 2. In 1 of them a tension pneumothorax developed requiring an exploratory thoracotomy. This was performed 20 days after the segmental resection and revealed a pinpoint opening in the basal bronchial stump. This defect was repaired with interrupted sutures. Continuous negative suction was applied and re-expansion was obtained.

The incidence of complications in this series of segmental resections is greater than that which attended routine lobectomy for the in-

cidence of empyema has been brought down to approximately 5 per cent. This segmental series however is an original group and there is reason to believe that a reduction in complications will follow. It should be pointed out that at the present time the conservation of uninvolved pulmonary tissue far offsets any effects of a temporary pleural infection which may occur. Functional studies have not been done in this group of cases. In the future when these studies can be undertaken we are confident that comparative studies will re-emphasize the importance of selective segmental resection for bronchiectasis.

CASE REPORT

L. B. student nurse 10 years of age. Patient had a chronic cough dating as long as she could remember. Recently the cough was productive of thick yellowish sputum daily. She had been having frequent cold episodes of pneumonitis and dyspnea. She was forced to give up work. Bronchographic studies (Fig 14 a) revealed cylindrical bronchiectasis in the middle lobe and anterior segment of right upper lobe and in the lingula and basal segments of the left lower lobe. On March 14 1945 a middle lobectomy and resection of the anterior segment of the right upper lobe was performed. On December 10 1945 the lingula and basal segments on the left were removed. Bronchogram (Fig 14 b) taken 3 months after second operation showed the remaining segments to be well re-expanded and free of bronchiectatic changes. The four segmental stumps can be seen. The superior segment of the left lower lobe now occupies the lower lung field.

CONCLUSIONS

1. A new method of removing a pulmonary segment applicable to any segment has been described. This method does away with the use of clamps or suture of the lung surface. The development of the intersegmental plane is precise, relatively avascular and not traumatizing.

2. The importance of considering the bronchopulmonary segment as a surgical unit in the management of bronchiectasis has been discussed. The frequency of bilateral and multiple segmental involvement has been pointed out.

3. Conservation of all healthy pulmonary tissue is desirable in all cases and obligatory in bilateral disease. It is vitally important that the surgeon limit the resection to diseased seg-

ments rather than remove entire lobes, segments of which are healthy and capable of respiratory function

CLINICAL EXPERIENCES WITH THE USE OF PENICILLIN TREATMENT OF INFECTIONS INVOLVING BONES AND JOINTS

H. J. McCORKLE, M.D. F.A.C.S., HENRY SILVANI M.D., W. E. STERN M.D. and
HELEN WARMER A.B. San Francisco, California

A CLINICAL investigation of the efficacy of penicillin in the treatment of infections involving the bones was begun on the University of California surgical services in April 1944 and continued until March 1945 after which the study was limited to bone grafting in infected areas and to the treatment of infections of the central nervous system and skull. During this period 87 patients with infections involving the bones and joints were studied. There were 58 cases with established infections of the large bones and joints (20 acute and 38 chronic) 4 cases with infections of the mandible and 25 cases with infections involving the bones of the skull (the latter with infections of the central nervous system will be reported elsewhere). Frequent bacterial cultures, blood penicillin levels and penicillin sensitivity tests accompanied the study of all cases (Table I).

ACUTE INFECTIONS INVOLVING BONES AND JOINTS

There were 20 patients with acute infections involving the large bones and joints. 7 had postoperative infections, in 4 infections followed injuries and 9 had acute hematogenous osteomyelitis.

The acute hematogenous infections included 7 cases of acute osteomyelitis (2 tibiae, 1 femur, 1 clavicle, 1 clavicle and sternum, 1 humerus, and 1 ilium) and 2 cases of acute septic arthritis (knee and hip joints). Five of the 9 patients had fulminating infections of 1 to 5 days duration with temperatures of 104 to 105 degrees F. and with blood cultures pos-

itive for hemolytic *Staphylococcus aureus* in 4 cases and beta hemolytic streptococcus, 1 case. The other 4 patients had been acutely ill for 2 to 8 weeks with temperatures 101 to 103 degrees F. with hemolytic *Staphylococcus aureus* infections but their blood cultures were sterile. The organisms were penicillin susceptible in all cases. In 5 cases a period of sulfonamide therapy given prior to penicillin treatment had failed to control the infection. Systemic penicillin was given by the intramuscular route at 3 hour intervals in all cases.

The initial dosage varied from 100,000 to 200,000 units per day. This was increased to 200,000 or 300,000 units per day within 24 to 48 hours if response to treatment appeared slow. The patients with fulminating infections usually became less toxic and the blood cultures became sterile within 48 to 72 hours after systemic penicillin therapy was started, but the temperatures declined rather slowly over a period of several days. The patients with less severe infections showed more rapid diminution of temperature and toxicity. The small abscesses and all infected joints were aspirated and penicillin solution was instilled into them. Usually concentrations of 5,000 units of penicillin per cubic centimeter were used in the abscesses and 1,000 units per cubic centimeter in joints. Infected joints and small abscesses usually became sterile after 48 hours of local penicillin therapy but aspirations and instillations were continued as long as fluid could be obtained. Large abscesses necessitated surgical incision for drainage in 4 of the 9 cases. Two of these were in the group of 5 patients with the fulminating infections, and 2 were in the group of 4 patients with less severe infections. Transfusions of blood were required in only 2 cases. All patients were kept in bed during the height of the infection and

From the Division of Surgery of the University of California Medical School. The work described in this paper was done under a contract, recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and the University of California.

INFECTIONS OF THE MANDIBLE

Four patients with serious infections involving the mandible were treated with penicillin. Two had chronic infections with penicillin susceptible hemolytic *Staphylococcus aureus*. One of these had an extensive chronic osteomyelitis and the other an infected fracture of the mandible with nonunion. Two patients had acute infections of the mandible: one had an acute osteomyelitis arising from a carious tooth with a large abscess involving bone and soft tissues and containing anaerobic staphylococcus, streptococcus, actinomyces and bacteroides; the other an osteomyelitis apparently from a carious tooth resulting in a fulminating bacteremia with beta hemolytic streptococcus.

The first patient had an operation for drainage and removal of sequestra, and received 1 800 000 units of systemic penicillin therapy over a period of 18 days. The wound was left open and healed promptly with an excellent result. The patient with an infected fracture had an open reduction including a sliding bone graft, done in conjunction with 3 700 000 units of penicillin given systemically over a period of 23 days. The wound healed without infection; the bone graft was successful and gave a satisfactory functional result.

Two patients had acute infections involving the mandible. Both apparently originated from infected teeth. One had a large abscess containing anaerobic streptococcus, staphylococcus, actinomyces and bacteroides. It was aspirated daily for 6 days, and 50 000 units of penicillin were injected daily for the first days and 25 000 units on each of three

CHRONIC INFECTIONS OF BONES AND JOINTS

In this group of 38 patients there were 12 with chronic infections resulting from hematogenous osteomyelitis, 18 with infected fractures, 5 with postoperative infections of the bone in a chronic phase, and 3 patients with tuberculosis of the bones, associated with chronic secondary pyogenic infections. Systemic penicillin therapy was given by the intramuscular route at 3 hour intervals. The improvement in appetite and nutrition of this group of patients within a few days after beginning systemic treatment with penicillin was striking. The drainage from the infected sinuses often became clear or opalescent, and in a few cases ceased entirely after a few days of penicillin therapy.

1. The chronic bone infections resulting from hematogenous osteomyelitis included 2 cases of osteomyelitis of the humerus, 2 of the tibia and 8 of the femur, in 1 of which the hip joint was involved. The bacterial flora in these patients were hemolytic and nonhemolytic *Staphylococcus aureus* (occurring alone and together), hemolytic and nonhemolytic *Staphylococcus* (combined) and mixtures of hemolytic *Staphylococcus aureus* with *Escherichia coli*, *Aerobacter aerogenes*, hemolytic *Staphylococcus albus*, alpha hemolytic streptococcus, beta hemolytic streptococcus and *Proteus vulgaris*. The organisms were penicillin-susceptible except the *Escherichia coli*, *Proteus vulgaris* and the alpha hemolytic streptococcus.

Aerobacter aerogenes which were very and the alpha hemolytic streptococcus which was very susceptible to penicillin.

penicillin therapy. All 10 of these patients had a course of preoperative penicillin therapy of 3 to 15 days duration averaging 8 days. The preoperative penicillin dosage varied from 100 000 to 200 000 units per day. Postoperatively systemic penicillin was continued for not less than 3 weeks and usually at least 6 to 8 weeks. The total amounts of systemic penicillin used in treatment in each case varied between 1 900 000 and 17 800 000 units averaging 4 499 000 units. The operations consisted of excision of all infected scars, granulations, sinus tracts, and sequestra, and excision of infected bone as far as was practical. The soft tissue wounds were closed at once in 6 of the 10 cases and 4 of these healed promptly without infection; one wound disrupted on the 5th postoperative day but subsequently healed slowly and satisfactorily, and the other wound became grossly infected (hemolytic *Staphylococcus aureus* and *Aerobacter aerogenes*) on the 7th postoperative day but subsequently healed and has remained healed. Three of the patients had secondary closures performed on the 14th, 16th, and 17th postoperative days, and all of these soft tissue wounds healed promptly and remained healed. The wound of 1 patient was left open and healed slowly but completely by granulation. Four patients (2 with primary closures and 2 with secondary closures) had local penicillin therapy given postoperatively through rubber tubes that were placed in the wounds at the time of operation and healing was rapid and complete in all 4 patients.

At the time this report was prepared there was no sign of activity of osteomyelitis in any of the 10 patients treated with operation in conjunction with penicillin therapy and the soft tissue wounds in all were completely healed. The 2 patients who were treated with penicillin therapy alone had excellent temporary results but both had a recurrence of infection after having remained healed for a year.

2. *Chronically infected fractures.* In the group of 18 patients with chronically infected fractures, the tibia was involved in 13 cases, the femur in 3 cases, and the humerus in 2 cases, 1 including the elbow joint. The organisms cultured from the wounds of these pa-

tients were hemolytic *Staphylococcus aureus* (occurring alone and with *Bacillus pyocyaneus*, *Escherichia coli*, beta hemolytic streptococcus and alpha hemolytic streptococcus), nonhemolytic *Staphylococcus aureus* (separately and mixed with *Streptococcus fecalis* plus *Clostridium welchii* and with gamma streptococcus), hemolytic *Staphylococcus albus* and a mixture of beta hemolytic streptococcus, *Streptococcus fecalis* and staphylococcus.

All of these patients required operation. They usually received a few days of preoperative penicillin therapy and in 3 cases several weeks of penicillin therapy preceded operations on infected fractures. Operation usually consisted of excision of infected scar, sinuses and granulations, and removal of infected and nonviable bone so that only well vascularized soft tissues and bone remained. At the same time open reduction of the fractures was performed. In 6 of these patients internal fixation with large metal plates was used and bone grafting was done in 13 of the patients. Position of the fragments was maintained with appropriate orthopedic methods of fixation. Multiple operations were required in some cases: 4 patients had 2 operations, 4 patients had 4 operations, and 1 patient had 5 operations. The additional procedures consisted of skin grafting, secondary closures, removal of metal plates and regrafting fractured bone grafts. Each operation was done in conjunction with a preoperative and postoperative course of penicillin therapy. There was no indication of dissemination of infection following any of the surgical procedures. The wounds were closed by primary suture in 16 of the 18 cases. Eight of these healed *per primam*; 3 had some necrosis of the soft tissue wounds due to closure under tension, 2 developed trivial superficial infections, and 3 wounds broke down with gross infection. The wounds of two of the 18 patients were left open and a trivial infection developed in 1 of these.

All patients received their systemic penicillin by intramuscular injection at 3 hour intervals. The daily dosage usually was 100 000 to 200 000 units. The total amounts of penicillin used in each case varied from 1 800 000 to 20 000 000 units, averaging 7,600 000 units.

per patient. An effort was made to maintain systemic penicillin therapy until all of the contaminated fracture area and overlying soft parts were vascularized completely and until bony repair was well begun. In some cases in which tension necrosis or superficial infection produced open wounds local bacteriostasis was maintained with penicillin ointment dressings. Four of the patients had postoperative local instillations of penicillin solution through catheters placed in the wounds at operation. In 3 of these healing was prompt and complete; in one the introduction of pyocyaneus delayed healing of the soft tissues but the final result was good. These tubes for local penicillin therapy were removed between the 10th and 14th postoperative days. Apparently firm union occurred at the fracture site in 13 of the 18 cases, 1 patient has fibrous union with poor function and 4 patients still have non union. At present the soft tissue wounds of 13 patients are completely closed, 2 have small superficial granulating areas and 3 have open infected draining wounds.

3. *Chronic postoperative bone infections*. Five patients had chronic infections of the bones resulting from previous operations. These included patients with the following conditions: an infected osteotomy of the tibia (poliomyelitis deformity), an infected revision of an amputation stump in the lower leg, an infected spinal fusion (performed for a fracture of the odontoid process), an infected hip joint arthrodesis (performed for traumatic arthritis) and an infection involving bones of the pelvis following an attempted lumbosacral fusion operation. The predominating organism found in this group was hemolytic *Staphylococcus aureus*, which occurred alone and with hemolytic *Staphylococcus albus*, beta hemolytic streptococcus, and in 1 case was mixed with nonhemolytic *Staphylococcus aureus*, gamma streptococcus and anaerobic non hemolytic streptococcus. All organisms were penicillin-susceptible *in vitro*. Each patient received a course of systemic penicillin consisting of 100,000 units daily for 3 to 11 days (average 8 days). In this group all 5 patients had operations for removal of infected and nonviable bone, scar granulations, and sinuses. The wounds of all patients were closed

by primary suture without drainage. Tubes were placed for postoperative local penicillin therapy in 2 cases. Postoperative systemic penicillin therapy was maintained for 14, 20, 43, 68 and 137 days respectively and the total penicillin dosage in these 5 cases was 1,400,000 units, 2,000,000 units, 4,095,000 units, 5,150,000 units, and 16,500,000 units.

The soft tissue wounds healed without infection in 3 of the 5 patients. In 2 patients *Proteus vulgaris* infections occurred postoperatively and produced serious acute infections followed by prolonged suppuration of the soft tissues but after several weeks both of these wounds healed completely. (One of the proteus infections occurred in a patient receiving local penicillin therapy through a rubber catheter; the other occurred in a patient who did not receive local penicillin therapy). Subsequently these 5 patients have exhibited excellent results; all wounds remaining healed.

4. *Tuberculosis of the bone and joints and secondary pyogenic infection*. The 3 patients in this group were treated with penicillin. One patient had tuberculosis of the spine (with thoracic to second lumbar) with multiple sinus tracts and secondary infection with a penicillin sensitive strain of hemolytic *Staphylococcus aureus*. He was given three separate courses of systemic penicillin therapy consisting of 100,000 units per day for 18 days, 14 days and 37 days, respectively. The secondary infection (hemolytic *Staphylococcus aureus*) responded slowly but apparently was controlled temporarily by penicillin therapy. However infection with the same organism recurred within a few weeks after each course of penicillin treatment. He received a total of 7,380,000 units of penicillin.

The second patient had tuberculosis involving the bones about the shoulder joint. The secondary infection in this case was a penicillin resistant hemolytic *Staphylococcus albus*. He received 2,100,000 units of systemic penicillin therapy over a period of 23 days without benefit. Suppuration from the draining sinuses was unchanged and the bacterial cultures remained positive for hemolytic *Staphylococcus albus*.

The third patient had long standing chronic tuberculosis of the knee joint with extensive

omyelitis of the femur and tibia. Cultures of his wounds grew a strain of hemolytic *Staphylococcus aureus* that was penicillin susceptible. Systemic penicillin was given preoperatively for 7 days (150 000 units per day) before the sinus tracts granulations were debrided and infected bone was excised thoroughly. Cancellous bone grafts from the ilium were placed in the large resulting defect and a plaster was placed for postoperative local penicillin therapy. The wound was closed without drainage and the extremity was fixed with steel plates in a plaster-of-paris cast. Postoperative local penicillin therapy consisted of 10 000 units per day for 10 days after which the tubes were removed. Systemic penicillin therapy was continued for 46 days. A total of 6 750 000 units of penicillin was given to this patient and the wound healed *per primam*. The bone grafts became vascularized and incorporated and a repair that produced complete arthrosis. One year later this patient was seen and had excellent function of the extremity. Systemic penicillin therapy proved to be a valuable adjunct to the surgical treatment of chronic infections involving bones. Complete surgical removal of all infected tissues and viable bone appears to be of primary importance in the successful penicillin treatment of most patients with chronic bone infections. Incomplete surgical removal of infected tissues is the most important cause for failure with penicillin therapy. In some cases it was impossible to remove all of the infected sclerosed bone, e.g. in a patient with osteomyelitis involving an entire long bone or large segment of the spine and in such cases recurrence of infection is inevitable. Internal fixation with metal plates almost invariably produced complications in the form of necrosis of the overlying soft tissues or delayed recurrence of the bone infection and it appears desirable that such plates when indispensable be removed at the earliest suitable time. Tension of the overlying soft tissues consistently resulted in

necrosis and infection with penicillin resistant organisms. Bone infections associated with very large open soft tissue defects were difficult to control because of reinfection through the open wound. Bone grafting in contaminated and infected areas was accomplished successfully in conjunction with penicillin treatment and several bone grafts in wounds that became infected postoperatively were saved by administration of penicillin.

Preoperative systemic penicillin for a period of several days appeared to be desirable and postoperatively it was found necessary to maintain systemic penicillin therapy until the soft tissues were healed and the bone defects were revascularized and had started their repair. This generally required at least 3 weeks and often several months depending on the size of the soft tissue and bony areas to be revascularized and on the vascularity of the tissues adjacent to the site of healing. Doses of 100 000 to 200 000 units daily were used but in most serious chronic infections it appears desirable to give at least 200 000 units per day. Inadequate dosage, i.e. small doses given infrequently or adequate doses given for too brief periods is ineffective. Whenever the infected area was accessible to local penicillin therapy the control of infection and healing seemed to take place more rapidly than with systemic penicillin therapy alone. Local penicillin treatment was particularly useful in controlling infection in large defects, and in areas contaminated with organisms that were somewhat resistant to penicillin levels obtainable in the blood but susceptible to higher concentrations of penicillin. It proved to be desirable to remove the tubes used for local therapy by the 14th postoperative day and it was necessary to avoid contamination with penicillin resistant organisms. Such contamination usually produces only prolonged suppuration of soft tissues but will permit reinfection of the bone unless penicillin therapy is maintained until healing takes place.

CARCINOMA OF THE PROSTATE

Review of 130 Cases Treated between 1940 and 1946

CHARLES PIERRE MATHE, M.D., F.A.C.S., and CARLOS E. ARDILA,
San Francisco, California

PHYSICIANS who deal with carcinoma of the prostate are appalled at the consistently fatal outcome of this disease.

In addition it carries a high operative mortality (approximately 20 per cent for radical removal and in our hands 11 per cent for lesser operative interventions). Careful rectal palpation may provide an early diagnosis however when carcinoma is occult and when it originates in the median or lateral lobes, this method fails. The hard nodule which is usually situated in the posterior lobe can be confused with localized inflammatory lesions and calculi. It is only at this stage that radical perineal prostatectomy can be carried out with any hope of cure and even then the disease may already have extended beyond the prostate via the lymphatics. The great majority of patients consult the urologist after cancer has extended well beyond the confines of the prostatic capsule, often associated with extensive metastases, uremia and cachexia. These cases present the immediate problem of affording relief of urinary obstruction and ameliorating toxic symptoms of the disease, thereby prolonging life.

Radical perineal prostatectomy is the method of choice for treatment of early carcinoma of the prostate. In advanced cases until recently the obstructing portion of the gland was removed suprapubically or perineally. These procedures have been gradually supplanted by transurethral resection as it provides a satisfactory channel and is a far more benign intervention. Two to three decades ago operative relief of obstruction was supplemented by radiation therapy either deep x ray or radium implantation. Recently increasing favor has accrued to the application of bilateral orchec-

tomy and oral administration of diethylstilbestrol. Deep x ray therapy is still used in a few cases in which pain persists in the metastatic manifestations of the disease. In advanced cases, transurethral resection, orchectomy and hormone therapy are followed by lower operative mortality, greater longevity and more marked relief of symptoms.

This communication consists of a report of 130 patients treated at St. Mary's Hospital and Southern Pacific General Hospital between January 1940 and January 1946. They add our observations to the experiences of others recorded in the excellent articles already published on this subject.

INCIDENCE

It has been repeatedly stated that approximately 20 per cent of the pathological specimens removed by prostatectomy reveal the presence of carcinoma. Out of 337 specimens removed by suprapubic or perineal prostatectomy at our two hospitals during the past 5 years, 8.4 per cent showed carcinomatous involvement. In a certain number of these, the presence of malignancy was suspected because of the hard consistency of the gland to rectal palpation in many clinical evidence was negative for cancer. According to Kahler in 51 per cent of autopsied cases in which a clinical or pathological diagnosis of prostatic cancer had been made, metastases were encountered. These may appear in any part or tissue of the body but have a predilection for the bony pelvis, spine, vertebrae, long bones, and lungs. They may also involve the testes and epididymides by retrograde lymph transport.

The current concept of carcinoma of the prostate is that it may coexist with simple hypertrophy and inflammation and does not represent carcinomatous degeneration of an adenoma. In this series, malignancy was en-

From the Department of Urology of St. Mary Hospital and Southern Pacific General Hospital, Read before the Second Mexican Cancer Congress, Guadalajara, Mexico, February 6, 1946.

countered in 77 of the 533 patients on whom transurethral resection was performed for benign hyperplasia and the smaller bladder neck obstructions. In the great majority of these 77 cases, carcinoma of the prostate was diagnosed prior to operation. A certain number showed the typical clinical picture of carcinoma as the gland was of stony hard consistency yet pathological study of the sections removed by transurethral resection failed to demonstrate this lesion. Two such cases are of interest. In the first castration was not carried out and resection was repeated because of recurrent obstructive symptoms. At the time of the second intervention pathological study revealed carcinoma. The second case presented a stony hard area in the region of the apex of the prostate and x ray evidence of metastasis in the spine. Sections removed were negative for carcinoma. The striking clinical improvement manifested by this patient after resection orchiectomy and diethylstilbestrol therapy left little doubt as to the true diagnosis. In all other cases carcinoma was found in a varying percentage of the

sections removed by transurethral resection. Age incidence ranged between 45 and 87 years.

DIAGNOSIS

The onset of carcinoma of the prostate is insidious and urinary disturbances occur late in the course of the disease. Careful palpation of the gland per rectum is of prime diagnostic importance. The plea for more frequent rectal examination of the prostate in all men over 50 has well been made by the numerous urologists who have written on the subject of prostatic carcinoma. In recent years an increasing number of internists have referred patients in whom this neoplasm was suspected by reason of the hard consistency of the gland discovered on routine examination by this method. The significance of hard nodules situated in the posterior lobe is accepted by every physician. Unfortunately similar hard areas located in the lateral and median lobes are inaccessible to digital palpation. Patients who had no reason to consult a urologist presented pain in the back due to bony metastasis in the pelvis and spine. Metastasis from prostatic car-

Unfortunately similar hard areas located in the lateral and median lobes are inaccessible to digital palpation. Patients who had no reason to consult a urologist presented pain in the back due to bony metastasis in the pelvis and spine. Metastasis from prostatic car-

Fig. a, left, Intravenous urogram showing filling defect at base of bladder due to obstructing cancer of prostate. b, Roentgenogram of dorsal spine demonstrating osteoplastic and osteolytic lesions of fifth and sixth vertebrae. Patient referred by neurologist because first symptoms appeared in spine.

cinoma was visualized on x ray examination by the attending orthopedist or neurologist to whom the patient had been referred. In these cases, rectal examination determined the original site of the tumor and patients were sent to the urologist for treatment. In moderately and fairly well advanced cases, cystoscopy reveals nodular encroachment into the vesical neck and prostatic urethra. The hard consistency of the gland is more noticeable on rectal palpation when cystoscope shaft is in place.

Retrograde or intravenous cystography shows nodular filling defects in the base of the bladder quite different from the picture seen in benign hypertrophy. We routinely carry out intravenous urography as it affords the opportunity of determining back pressure changes and concomitant lesions in the kidney as well as characteristic filling defects in the base of the bladder. In every instance of suspected carcinoma of the prostate roentgenograms are made of the long bones, bony pelvis spine, and lungs in an effort to determine the presence of metastasis. Its appearance is often confused with that of hypertrophic arthritis and other forms of osseous hyperplasia par-

ticularly Paget's disease. I recall a patient treated by a competent internist for hypertrophic arthritis. Complete retention of urine brought this patient to our service and examination revealed advanced carcinoma of the prostate with metastasis to the spine. The reaction of bone to metastatic carcinomatous invasion is osteoplastic. Normal cancellous structure is replaced by the blurred outlines of new bone formation. Following orchiectomy the bone usually becomes denser its outlines smoother and clearer as healing takes place (1).

Determination of the acid and alkaline phosphatase levels, as originally proposed by Scott and Huggins, offered promise in the diagnosis of carcinoma of the prostate with metastasis. However Huggins subsequent study of 47 men with advanced prostatic carcinoma showed 50 per cent elevation of phosphatases and 50 per cent normal (4). We have made phosphatase studies in a number of patients presenting this disease and find it unreliable. In fact, in the majority of cases reported in our series in which blood acid phosphatase tests were carried out, the concentration was found to be within normal limits.

Fig. 3 a, left, Roentgenogram of pelvis showing advanced osteoplastic and osteolytic involvement of bones making up pelvic girdle. Transurethral resection, bilateral orchiectomy and stilbestrol therapy prolonged this patient's life. b Roentgenogram of chest demonstrating late metastasis in lung and ribs.

When it is elevated this finding aids in confirming the diagnosis already made by other clinical observations. In addition it assures the rationale of orchiectomy.

Direct biopsy of prostatic tissue has been used; we do not employ it as a routine because the piece removed may be free of disease in an otherwise carcinomatous gland; more over this intervention may serve to hasten dissemination of cancer cells.

SYMPTOMATOLOGY

Unfortunately the patient presents no symptoms in the early stages of the disease at which time carcinoma is usually localized in the posterior lobe. Loss of weight, anemia, cachexia and pain often precede urinary disturbances. It is at this time that the astute attending physician may detect the elusive disease by carrying out skillful rectal examination. Later invasion of the vesical neck and posterior urethra takes place causing frequent difficult, and painful urination. In cases in which carcinoma occurs concomitantly with benign hypertrophy the well known obstruc-

tive symptoms of prostatism are present. Occasionally prostatic cancer metastasizes early and pain resulting from extension to the spine, pelvis, long bones and lungs are the only manifestations present. Cases have been reported in which the first symptoms were due to metastases occurring in the brain, thyroid, liver, testes and epididymes. Not infrequently the internist, orthopedist and neurologist are consulted because pain in the osseous system predominates. These specialists are rapidly becoming familiar with the characteristic roentgen appearance of bony metastasis of cancer of the prostate and refer more patients to the urologist for present day treatment.

TREATMENT

Radical perineal prostatectomy as proposed by Young and modified by Colston and by Belt is the treatment of choice for eradication of early carcinoma of the prostate. The entire gland including its capsule, the adjacent vesical neck, prostatic urethra, and seminal vesicles are removed *en bloc*. Unfortunately this operation is of no value in occult carcinoma.

nor does it provide for removal of the regional lymphatics which become involved early (51 per cent according to Kahler). As the disease progresses encroachment into the prostatic urethra and bladder neck takes place and the problem becomes primarily and often urgently one of relieving urinary obstruction. At this stage, the disease has advanced to a point far beyond the reach of radical intervention. Until about 1932 removal of obstructing cancerous tissue was accomplished suprapubically or perineally. Since that time the perfected operation of transurethral resection has proved to be the more benign procedure even if it must be repeated. By providing an adequate channel for urinary outflow back pressure on the kidneys is relieved early death from uremia prevented and life prolonged. At best life expectancy in these elderly men is short surgical risk is poor and the comfort of the patient is the primary motive. Our good results added to those reported by many other authors, are a testimonial to the efficacy of this operation. It offers the additional advantage of detecting and relieving concomitant lesions of the bladder e.g. papillomas and small calculi.

The splendid work of Huggins and his associates on orchiectomy (6) added an effective weapon to combat this incurable disease. Their observations concerning regression of the cancerous process in the gland itself as well as in its metastatic manifestations in the skeletal system and soft tissues following orchiectomy were readily accepted and corroborated by numerous surgeons. Some prefer to employ radiation therapy to the testicles rather than orchiectomy the results of the two procedures are of equal value. Orchiectomy has given us very good results however we prefer to relieve urinary obstruction by transurethral resection as without this auxiliary intervention the patient may succumb from uremia before sufficient regression of the obstructing cancerous gland has taken place. A case in point is that of Dr. H. aged 70 years, who entered the hospital with advanced cancer of the prostate. He presented considerable retention of urine and elevated acid phosphatase. Orchiectomy was performed transurethral resection was refused and the patient died from uremia 3 weeks later. One should not de-

pend on orchiectomy and stilbestrol therapy alone. Opinion is divided regarding the best time to perform orchiectomy (8). Some employ it only after metastasis has taken place and is advanced others contend that it should be carried out as soon as the diagnosis is made. In the presence of metastases we always advise it, and in active cases associated with pain we recommend its early application.

Further studies of Huggins (5) revealed that in the majority of cases ingestion of stilbestrol caused regression of cancer of the prostate and of its metastatic manifestations throughout the body. This female hormone exerts an antagonistic effect on androgens which are normal in the prostate and excessive in the presence of cancer of that gland. Hormone therapy (oral diethylstilbestrol) should be instituted as soon as the diagnosis is made. There are certain cases of advanced cancer with extensive metastases in the bony structures and lymph and vascular systems in which pain due to pressure on adjacent nerve is not relieved by orchiectomy or hormone therapy. In these deep irradiation may be utilized for relief of intractable pain.

ANALYSIS OF CASES

In reviewing our 130 cases on which operation was carried out for carcinoma of the prostate, 12 (10.8 per cent) failed to reveal the presence of cancer in the sections removed by transurethral resection. In many of these the gland presented stony hard consistency to rectal palpation there was loss of weight, uremia, cachexia etc. and x ray evidence of metastasis in the bony structures and lungs. In some patients, all sections removed demonstrated active carcinoma in others, it was found in only 1 out of 8 or more sections. When clinical evidence pointed to prostatic cancer and the pathological specimens were negative for cancer the acid phosphatase test was of little value to us in clarifying the diagnosis as has already been pointed out by Huggins and many others. In some cases, a second resection became necessary for relief of recurrent urinary obstruction later histological examination revealed the elusive carcinoma.

It must be realized that in carrying out transurethral resection one is concerned with

removal of the obstructing tissue alone and that the cancerous process which was so well detected by rectal palpation may not have involved the intraurethral tissues. Our observations clearly show that in 10 per cent of cases carcinoma of the prostate was absent in tissue removed by resection. Yet in these the clinical picture was typical of advanced carcinoma. Therefore in attacking the problem one must be guided by the clinical diagnosis, although one must always strive to secure laboratory substantiation. This was obtained in 90 per cent of our cases in the 10 per cent in which it was lacking we felt justified in proceeding with present day methods of relief.

Carcinoma of the prostate was encountered in 28 glands removed by suprapubic enucleation. In the great majority of these, it was not suspected prior to operation. In 8 the gland was fairly hard to rectal palpation and carcinoma was believed to be present. When early carcinoma of the prostate was suspected we elected radical perineal prostatectomy in the very early case and transurethral resection in all others. Transurethral resection was carried out in 77 patients. It was necessary to perform secondary resection for recurring obstructive symptoms in 4. Radical perineal prostatectomy was performed in 3 (2.3 per cent). These are living and well 3, 4 and 5 years after operation. Subsequent orchiectomy and stilbestrol therapy was carried out in 2 of these. The fact that so few cases of early carcinoma came to us at a time at which it was possible to carry out radical operation substantiates the opinion of other urologists, that earlier diagnosis should be made by the attending physician. Orchiectomy was carried out in 94 patients. When the favorable results obtained by this beneficial operation were explained to the patient we had little difficulty in securing his consent. Nine presented no urinary obstructive symptoms, and were treated by orchiectomy alone. We prefer to carry out transurethral resection in cases in which retention is present, and not to rely on orchiectomy to bring about regression of the growth thereby permitting free urination. It affords the additional advantage of corroborating the diagnosis by histological examination. In certain cases in which we counted on orchiectomy

alone death from uremia ensued. Among those who refused orchiectomy were two physicians.

Thirteen patients were not treated by prostatectomy or transurethral resection. Some of these were in the advanced stages, and died shortly after cystotomy for urinary retention due to impassable obstruction. x ray therapy for metastasis and medical care alone. Of the 108 patients on whom operation was carried out, 12 (11 per cent) died within 6 weeks. We wish to comment on the greater mortality following removal of the prostate for cancer (11 per cent) than for benign hypertrophy (3.5 per cent). Two patients succumbed after suprapubic prostatectomy for benign hypertrophy in which carcinoma was encountered and 10 after transurethral resection for known carcinoma. Causes of death were pulmonary embolism, pneumonia, cardiac collapse and other complications or intercurrent disease. An important number died of carcinomatosis and there was no noticeable abatement of the disease process. It is interesting to observe that 7 out of 13 cases in which no operation on the prostate was carried out promptly expired, 5 after medical care alone (45 per cent), 2 after cystotomy for complete retention due to impassable obstruction (100 per cent) and 1 after orchiectomy alone (11 per cent). The mortality following operative intervention for carcinoma of the prostate is high because we are dealing with patients in the advanced stages of cancer, debilitated by toxemia and varying degrees of uremia. Except in the occasional early case treatment consisting of transurethral resection, orchiectomy and hormone therapy is merely palliative. However the relief of symptoms and prolongation of life which it offers makes the risk worth while—11 per cent mortality as shown by the review of this series of cases.

Out of 108 cases in which surgical intervention was carried out for carcinoma of the prostate we were able to follow 50. In these orchiectomy and stilbestrol therapy supplemented transurethral resection, radical perineal prostatectomy, and suprapubic enucleation. Eighty per cent were definitely improved, 20 per cent showed little if any amelioration and these rapidly succumbed to the disease.

Since 1942 when orchiectomy and stilbestrol therapy were proposed as an additional means of combating this disease, 9 survived three years, 14 two years, 10 one year and 17 less than one year. Of unusual interest is the case of Mr. A. aged 76 years, who was completely disabled because of difficult urination and intense pain due to metastasis. He had been abandoned to morphine therapy. Transurethral resection, orchiectomy and stilbestrol therapy were carried out 1 year ago. Relief was so great that he returned as a shipyard worker within 6 weeks and has been active ever since. A number of similar cases in this series bear evidence to the efficacy of this treatment. Of particular interest is the case of Mr. D. colored, aged 65 years. On December 1, 1944, transurethral resection and bilateral orchiectomy were carried out. The removed sections showed active carcinoma. Rectal examination was made on September 21, 1945, at which time digital and cystoscopic investigation revealed clinical absence of carcinoma. A number of patients who refused orchiectomy at the time of transurethral resection accepted it 1 to 2 years later on account of increasing pain due to bony metastasis which persisted in spite of stilbestrol therapy. Of equal interest is the case of Mr. J. K. aged 58 years, on whom suprapubic prostatectomy was carried out in March, 1942. Carcinoma was encountered within the adenoma and bony metastases developed 1 year later. He refused orchiectomy, was placed on diethylstilbestrol therapy and is still enjoying good health.

SUMMARY

One hundred thirty cases of carcinoma of the prostate treated between 1940 and 1946 are reviewed. Operative intervention was employed in 108: transurethral resection in 77, radical perineal prostatectomy in 3, and suprapubic enucleation in 28. Eleven advanced cases received medical care or x-ray therapy only. In 2, cystotomy for relief of retention due to impassable obstruction in 9, orchiectomy and stilbestrol therapy alone were carried out.

Twenty-eight of the 337 specimens of prostate removed for benign hypertrophy in which carcinoma was not suspected revealed carcinoma (8.4 per cent).

Mortality for operative interventions for cancer of the prostate is 11 per cent in 104 cases, as compared with 3.5 per cent in 337 prostatectomies for benign adenoma during the past 5 years.

Rectal palpation is still the sole criterion of early diagnosis. Only 3 in our series were detected early enough to justify radical perineal prostatectomy. Cystoscopy, cystography and x-ray examination of the skeletal system and lungs corroborated the presence of varying stages of cancer with or without metastasis. Elevation of blood acid phosphatase, although of great aid when present, was of no value in elusive disease.

In 11 per cent of our 77 patients treated by transurethral resection which presented positive clinical evidence of carcinoma, histological examination of the pathological specimens failed to reveal the presence of cancer. The favorable subsequent clinical course warrants our contention that one should proceed with transurethral resection, orchiectomy and stilbestrol therapy in such cases.

Radical perineal prostatectomy is the treatment of choice in early carcinoma. Unfortunately, it is of no value in occult cancer and does not provide for removal of regional lymphatics. Transurethral resection, supplemented by stilbestrol therapy, orchiectomy and deep irradiation for intractable metastatic pain resulted in definite improvement and increased longevity in 80 per cent of our patients.

Although we are dealing with a progressively fatal disease, the present day palliative measures at our command are justified as they relieve urinary obstruction and ameliorate toxic symptoms, thereby prolonging life.

STUDIES ON ANURIA

Effect of Infusion Fluids and Diuretics on the Anuria Resulting from Severe Burns

WILLIAM H OLSON and H NECHELES M D Ph.D., Chicago, Illinois

IF an anuria is not relieved by physiological processes or by therapy death invariably ensues. Many types of diuretic agents and infusion fluids have been employed with varying degrees of success to relieve anuria or oliguria following hemoglobinemia. This study attempts to evaluate the agents and fluids which have been used on human beings. We have found that some agents were far more effective than others and that the accepted therapeutic practice was not always the most effective. Although the agent found to be most effective in our study has been infrequently employed it was successful when used in a limited number of human cases. We believe therefore that our results can be applied in the treatment of patients with anurias following severe burns, transfusion reactions, crush syndrome and in toxic hemolytic anurias, and we therefore submit our experiences and our results to the medical profession.

In an earlier study of anuria in experimental shock we differentiated three distinct types which we designated the 'burn', 'crush', and 'hemorrhage' (reduced blood volume) anurias (17). The 'burn anuria' was selected for the more extensive studies because it is acute and develops rapidly and therefore may be studied more easily in the experimental animal. Severe thermal trauma produces a severe hemoglobinemia consequently if the kidney is able to excrete urine, hemoglobinuria follows. In patients burned in the Coconut Grove disaster Shen and co-workers described hemoglobinemia and hemoglobinuria. We believe that a review of the literature (5, 10, 19, 20) together with our data indicates

Aided by a grant from the A. B. Kuppenheimer Fund. The Department is in part supported by the Michael Reese Research Foundation. Preliminary reports were given at the Central Soc. Clin. Res., 1944, 17, 20, and Proc. Inst. M. Chicago, 1945, 5, 6.

that the damaged renal function produced by burns is similar to that following hemolysis from incompatible blood transfusion (transfusion kidney), blackwater fever, and other hemolytic diseases. Some features are also similar to the renal impairment in the crush syndrome. The common factor in all of these cases is an intravascular hemolysis due to the sudden and rapid destruction of erythrocytes or muscle cells. This destruction liberates large amounts of hemoglobin or myoglobin and fragments of destroyed cells into the systemic circulation. In addition the factor of damage to renal tubular epithelial cells by anoxia and toxins plays a rôle. Ross states that the mortality rate is high in most diseases associated with hemoglobinuria.

In our studies of anurias which followed experimental procedures leading to shock we felt the need for determining the relative effectiveness of present methods of relieving these anurias. A number of workers in England have observed and treated impairment of renal function due to crush or compression of limbs (crush kidney syndrome). Bywaters in 1944 has suggested the following therapy for the crush kidney: administration of fluids and alkali, concentrated serum, mercurial diuretics and in established renal failure de-capsulation. Maitland in 1941 (12) recommended the use of isotonic sodium sulfate for the treatment of the crush kidney and later reported good results (13). Shepherd in 1942 used a slow intravenous drip of isotonic sodium sulfate solution and in view of the tubular renal lesions was against giving any drastic diuretics such as mercurials. He feels that 'blood transfusion is contraindicated as the inevitable degree of hemolysis will throw additional strain on secretion'.

We felt that conclusions as to the most effective treatment are difficult to establish

Chart. The shaded columns represent the amount of free hemoglobin in the plasma, in milligrams per cent. The black columns represent the average drops of urine per 5 minutes excreted after the 1st infusion.

from observations on human subjects alone and Bywaters bears this point out in his article by saying that little is known about the effects of therapy.

Experimental procedure. Large healthy male dogs were used for all experiments. They were kept under deep nembutal anesthesia throughout the experimental period. The abdomen was opened and each kidney was isolated and connected to a healthy dog in order and counter (6). A kymograph the urinary blood pressure kymograph so that between blood pressure was possible and the treatment could be repeated determinations dioxide, hemoglobin hemoglobin in the plasma number of experiments kidneys were performed these were glo

The seventy experiments could be of hemoglobins of free hemoglobin as a basis for comparing infusion fluids and experiments isotonic for the control infusion. In most experiments a period of 1 to 2 hours was created at a constant flow burned severely. Complications occurred within experiments. The onset of hemorrhage anuria. The samples were drawn for the first intravenous infusion 15 cubic centimeters.

At the termination of the chemical study.

Results. The performed for the experiments of 21 thermal trials in an earlier paper were able to for the 43 the first in this in the

the intravenous infusions of saline. In Experiment 2 (not shown on Chart 1) a small amount of urine, 14 drops per 15 minutes, was excreted after the infusion of saline. However the free hemoglobin was only 580 milligrams per cent. We have found that saline has very little beneficial effect on the anuria when the free hemoglobin in the plasma is above 1200 milligrams per cent. In Experiment 6 (Chart 1) 6 per cent gelatin had a slight diuretic effect when the free hemoglobin was 1100 milligrams per cent. In Experiment 8 2 per cent urea in 6 per cent gelatin had a slightly better effect than gelatin alone although the plasma hemoglobin was higher. In Experiment 9, 2 per cent urea in saline had an even more marked diuretic effect when the free hemoglobin was as high as 1850 milligrams per cent. The addition of urea made saline solution an efficient diuretic. This is shown in Experiment 4 in which no urine was excreted although the levels of free hemoglobin were similar in Experiments 4 and 9. In Experiment 10 we found that Ringer's lactate solution was superior to saline or gelatin. It had some beneficial effect on urinary flow even though the plasma hemoglobin was as high as 1540 milligrams per cent. The therapeutic value of saline was improved by addition of caffeine. In Experiment 12, a distinct diuretic action was shown by this combination when the free hemoglobin in the plasma was 1710 milligrams per cent. A combination of 2 per cent urea, 5 per cent dextrose and caffeine in 1/12 molar lactate solution was somewhat toxic, and we discontinued further attempts with this "shot gun" type of therapy. In Experiment 15 we found that 2 per cent urea in 1/6 molar sodium lactate solution had no effect on the anuria produced when the animal was severely damaged (free Hb was 2700 mgm. %).

At this stage of our study we concluded that certain infusion fluids were more effective than others in overcoming the anuria of burns but that a limit could be reached in effectiveness when such severe burns were produced that the plasma hemoglobin was extremely high. In Experiment 19 on Chart 2 heparinized plasma produced a distinct excretion of urine when the free hemoglobin in the plasma was only 1195 milligrams per cent. But when the

Chart 2. The shaded columns represent the amount of free hemoglobin in the plasma, in milligrams per cent. The black columns represent the average drops of urine per 15 minute intervals, excreted after the last infusion.

kidneys were more severely damaged as in Experiment 18 in which the free hemoglobin was 2450 milligrams per cent, no urine was excreted after three infusions of plasma. Five per cent dextrose in Ringer's solution was more effective in Experiment 30 than saline alone in Experiment 4, but when the animal was more severely damaged, as in Experiment 22, dextrose Ringer's had no effect. The next type of fluid tried was a combination of 0.87 per cent sodium bicarbonate in saline. When free hemoglobin was low following the burn this mixture had a marked diuretic action as shown in Experiment 28 (plasma hemoglobin was 1170 milligrams per cent, and urine flow 195 drops per 15 minutes). However, when the free hemoglobin was 2300 milligrams per cent as in Experiment 29 bicarbonate and saline had no effect on the burn anuria. We finally tried isotonic sodium sulfate solution as suggested by Matland for the treatment of the crush kidney syndrome (12). Experiment

Chart 3. Urine from both kidneys is recorded as the average number of drops per 5 minutes. Plasma hemoglobin (free Hb) is recorded in milligrams per cent, and the hematocrit (Ht) as per cent.

32 showed that this fluid could produce a marked diuresis, even when the amount of free hemoglobin was as high as 2250 milligrams per cent. In Experiment 20 isotonic sodium sulfate solution was used free hemoglobin was 2350 milligrams per cent, and urine was excreted at the rate of 200 drops per 15 minutes. In Experiment 21 free hemoglobin was 2080 milligrams per cent yet the kidneys excreted 140 drops per 15 minutes after three infusions of sodium sulfate. To date this fluid has been the only agent that will, in all cases, stimulate the kidneys to excrete after a severe burn. It is the only fluid that has been found to have a marked beneficial effect on the burn anuria when the free hemoglobin in the plasma is above 2000 milligrams per cent, and no failure of response to sodium sulfate infusion was encountered in any of our experiments.

A closer comparison of certain experiments is enlightening when they are selected on the basis of similar concentrations of plasma hemoglobin after the burn. Chart 3 illustrates the effect on the burn anuria of plasma in Experiment 19 and the effect of saline plus an alkali (NaHCO_3) in Experiment 28.

The control values in Experiment 19 (left) are as follows: urine 14 drops per 15 minutes, hematocrit, 52 per cent, free hemoglobin, 10 to 20 milligrams per cent. One hour after the burn the hematocrit had risen to 65 per cent, free hemoglobin was 1175 milligrams per cent and urine excretion stopped. The first plasma infusion caused only a slight excretion of urine, less than 1 cubic centimeter; the second infusion was followed by an average of 19 drops per 15 minutes, but after the third infusion urine secretion fell to 12 drops per 15 minutes. The total urine excreted after a total plasma infusion of 750 cubic centimeters was only 19 cubic centimeters over a period of 3½ hours. There was however a marked decrease in both plasma hemoglobin and hematocrit. This was probably due to the diluting effect of the plasma only. The control values in Experiment 28 were urine 20 drops per 15 minutes, hematocrit 43.5 per cent, free hemoglobin 15 to 20 milligrams per cent. One hour after the burn the hematocrit had risen to 66 per cent, the free hemoglobin to 1170 milligrams per cent (similar to the concentrations in the plasma experiment) and urine excretion

OLSON NECHELES STUDIES ON ANURIA

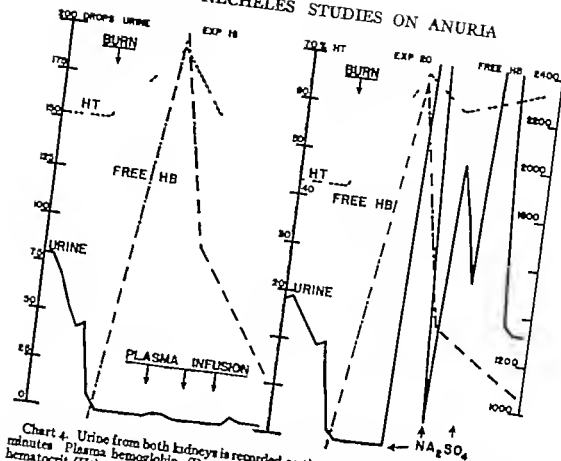

Chart 4. Urine from both kidneys is recorded as the average number of drops per 15 minutes. Plasma hemoglobin (Free Hb) is recorded in milligrams per cent, and the hematocrit (Ht) as per cent.

tion had dropped to zero. The first infusion of the sodium bicarbonate plus sodium chloride solution produced only a small amount of urine averaging 13 drops per 15 minutes and a total volume of 6 cubic centimeters. The second infusion produced considerably more urine, 67 drops per 15 minutes and a total volume of 32 cubic centimeters and the third infusion an average of 195 drops per 15 minutes and a total volume of 92 cubic centimeters of urine. Altogether 130 cubic centimeters of urine was excreted in response to 708 cubic centimeters of infusion fluid. The drop in free hemoglobin is greater in this experiment than in the previous one in which plasma was used. There was a 75 per cent decrease in the free hemoglobin and a 120 per cent decrease in the hematocrit. In Experiment 19 a 60 per cent decrease in free hemoglobin but a 31 per cent decrease in hematocrit occurred.

Chart 4 compares the results of infusions of plasma and isotonic sodium sulfate (Experiments 18 and 20). Both animals were given more severe burns than those in Chart 3. The values for free hemoglobin after the burn were

2450 and 2350 milligrams per cent, respectively. The three plasma infusions in Experiment 18, totaling 795 cubic centimeters produced less than 1 cubic centimeter of urine. The three sodium sulfate infusions in Experiment 20 totaling 570 cubic centimeters produced 266 cubic centimeters of urine and an immediate diuretic effect was obtained with the first infusion. In the experiment in which plasma was used the decrease of the hematocrit was 25 per cent, and the decrease in plasma hemoglobin was 59 per cent. On the other hand when sodium sulfate was used the decrease in hematocrit was only 5 per cent although free hemoglobin decreased 49 per cent. This seems to indicate that more free hemoglobin was removed from the blood following sodium sulfate infusion than after plasma infusion and that the action of the blood was largely that of a diluent of the

were selected from this group on the basis that they demonstrated the pertinent findings of our study while the remaining experiments are confirmatory. Attention should be drawn to the agent employed, to the amount of free hemoglobin in the plasma after the burn, and to the amount of urine excreted. It will be noted that other diuretic agents had little or no effect when the damage to the kidneys was great. These agents were mercuric, aminophylline, thiamine chloride, ascorbic acid, niacin, and vitamin B₁ and B₂.

Kidney function tests were performed in the sodium sulfate treated animal only because that diuretic agent was the only one capable of stimulating sufficient urine excretion for these tests, even in the severest type of burn. Table II gives the significant experimental data obtained, when glomerular filtration rate was studied before and after the thermal trauma and subsequent infusion of sodium sulfate. In the control Experiment G F 1 there was a decrease in filtration rate of 12 per cent although no trauma was inflicted upon the animal, except that of the anesthesia and the operative procedures. In Experiment G F 2 an 82 per cent decrease in rate occurred but in G F 3 with a slightly higher plasma hemoglobin, the decrease was only 44 per cent. It should be noted that while the decreases quoted above were decreases from the control values, the differ

ences from 100 per cent represent absolute increases from the anuria previous to infusion with sodium sulfate. A combination of sodium sulfate and plasma did not improve the filtration rates over those obtained with sodium sulfate alone as shown in Experiments G F 4 and 5. In all experiments with sodium sulfate the volumes of urine excreted were excellent as compared with the control volumes.

Table III summarizes the data obtained when both glomerular filtration and effective renal plasma flow were studied before and after the burn and subsequent treatment with isotonic sodium sulfate solution. The first four experiments showed similar results: a greater decrease in renal plasma flow than in glomerular filtration rate while in Experiment PAH 5 the opposite occurred. The greater change in renal plasma flow in Experiments PAH 1 to 4 was demonstrated by a marked increase in filtration fraction as shown in the table. Two factors which may cause an elevated filtration fraction are, first a vasoconstriction of the renal arteries and second a marked damage to the renal tubules. Both are probably responsible for our results because the renal tubules are damaged and may be blocked in renal insufficiency associated with hemoglobinuria (15) and vasoconstriction occurs after injections of hemoglobin (14).

DISCUSSION

In the present studies, we were able to produce an acute anuria in dogs which was

treated effectively in every instance with isotonic sodium sulfate while alkali solutions were distinctly inferior. This was surprising because many authorities recommend the use of alkaline solutions and these are widely used at present in an effort to alkalinize urine in patients with hemoglobinuria from transfusion reaction (4) blackwater fever (19) and crush syndrome (3). In a recent article Lund recommends the use of alkalies (sodium bicarbonate or sodium lactate) for the treatment of hemoglobinemia and hemoglobinuria in occasional cases of very extensive deep burns (10). We will not deny that in many cases alkali treatment is sufficient; our experiments show that alkaline solutions are effective when the free hemoglobin in the plasma is below 1500 milligrams per cent. Above this level however isotonic sodium sulfate infusion is necessary to start the excretion of urine.

Recently Macraith and Havard warned strongly against the use of intensive alkali treatment in black water fever. They claim that the mortality of blackwater fever has not diminished since intensive alkali treatment was introduced. They also state "The persistence of the high mortality in blackwater fever shows that any benefit that intensive alkali treatment may have for individual patients is counterbalanced by the deleterious effects it has on others. The danger lies in the production of an alkalosis and this condition may be sufficient to kill the patient."

A careful review of the literature as to the dangers of alkalosis to kidney function reveals

that many observers were cognizant of this fact. Kirsner and Palmer described a number of patients with peptic ulcer who had normal renal function before treatment with calcium carbonate developing markedly depressed renal function during alkalosis. The Army Malaria Research Unit at Oxford (1) recently described the effects of large doses of alkali in normal men and found that all subjects had disturbances of renal functions. Their conclusion was that large doses of alkali should not be administered in a condition in which renal failure may supervene.

Considerable disagreement is present as to the mechanism of impaired renal function in the presence of hemoglobinemia and hemoglobinuria (19). The most persistent theory first introduced by Baker and Dodds (2) is that acidosis occurs in many cases of hemoglobinemia and that the hemoglobin damages the kidney only if the urine is acid due to the precipitation of acid hematin in the renal tubules with subsequent mechanical blockage of urine flow. This is the basis of the alkali therapy. Wakeman and co-workers in 1932 were first to question this theory in conjunction with blackwater fever. They state: "No support has been found for the theory that acidosis occurs in blackwater fever to offer an indication for alkaline therapy. The administration of bicarbonate in the cases described led to the development of alkalosis. Another very important piece of work frequently overlooked is that of Foy and Kondi who described cases of anuria frequently developing in patients who had slight hemolysis and passed alkaline urines and other patients who failed to develop anuria, although they had marked hemolysis with acid urine (6). In 1943 these men carefully examined the alkalization hypothesis and concluded that there was insufficient evidence to warrant any statement as to the efficiency of alkali solutions in either preventing or relieving the oliguria and anuria in blackwater fever incompatible transfusions and crush injuries (5)."

What are the dangers of the use of isotonic sodium sulfate? This solution has consistently been nontoxic in all of our experiments. Peters states in a recent review: "Because of the efficiency with which sulfate is excreted

and its comparative physiological inactivity, its salts have a strong diuretic effect. The sulfate ions, when being excreted, promote the chloride ion, while many other diuretics cause a depletion of chloride ion. Therefore, in cases where there is a possible diminution of chloride concentration as in burns (5), sodium sulfate is the diuretic agent of choice due to its mechanism of conserving chloride ion."

Relatively large amounts of isotonic sodium sulfate have been effective in preventing the anuria in the crush syndrome. Marshall originally suggested the use of sodium sulfate up to a maximum of 3 liters per day in men with crush injuries, given by constant drip intravenously (12). In several cases a total amount of 8 liters was given during the first 11 days with complete recovery (13). We believe that it might be possible to give an initial injection of sodium sulfate to start the urine flow and then follow this by other diuretic agents. In Experiment 43 we obtained the highest level of plasma hemoglobin, 4096 milligrams per cent. The first injection of sodium sulfate caused a slight excretion of urine. The plasma hemoglobin was lowered to 3,300 milligrams per cent, $\frac{1}{2}$ hour after the injection. After this an injection of 8 per cent gelatin solution was able to stimulate some urine formation. This agent was one of the poorer types of diuretics, yet it was able to cause urine excretion when the plasma hemoglobin was above 3000 milligrams per cent, because of the priming effect of the sodium sulfate.

Ross concludes his excellent review with several important statements which we feel should be stressed. "Hemoglobin must remain in its normal intra-erythrocytic position if health and normal body function are to be maintained. Although capable of transporting oxygen and of sustaining life when in solution in the plasma, the escape of large quantities of hemoglobin from erythrocytes into the plasma is almost invariably followed by adverse symptoms and frequently by death. Red or black urine, the danger signal indicating extensive intravascular hemolysis, must always be taken seriously; its cause determined and appropriate therapeutic measures immediate."

diately instituted' Our study indicates that isotonic sodium sulfate is a very valuable therapeutic agent in anurias resulting from the hemoglobinemia of severe burns.

SUMMARY AND CONCLUSIONS

1 With the type of burn employed an acute anuria was produced in which the extent of renal dysfunction could be correlated with the amount of free hemoglobin in the plasma

2 Plasma and saline were the least effective infusion fluids for combating the anuria. The following solutions in increasing order of effectiveness were superior sodium lactate 5 per cent dextrose in Ringer's solution 2 per cent urea in saline and 0.9 per cent saline with 0.87 per cent sodium bicarbonate. They were effective in instances in which kidney damage was not great

3 Isotonic sodium sulfate was the most effective agent in combating the burn anuria. It has overcome anuria in all cases in which it was tried. The most severe anuria was one in which the free plasma hemoglobin was over 4000 milligrams per cent.

4 The concentration of free hemoglobin in the plasma was most effectively decreased by the use of sodium sulfate. Infusions of plasma gave an apparent reduction of plasma hemoglobin but this was demonstrated to be associated with the more prolonged diluting effect of the plasma.

5 The following substances had very little diuretic effect when kidney impairment was great mercupurine, aminophylline, thiamine, chloride, ascorbic acid, nicotinic acid, vitamin B₁, and vitamin B₂.

6 In complete anurias, glomerular filtration rate and effective renal plasma flow were partially restored following the infusion of sodium sulfate. The greatest improvement occurred in the filtration rates.

7 The use of isotonic solutions of sodium sulfate is recommended in the treatment of the anuria of burns and of related anurias.

DIVERTICULA OF THE STOMACH AND DUODENUM

Treatment by Invagination and Suture

L. KRAEER FERGUSON M.D., and CHARLES S. CAMERON Jr. M.D.
Philadelphia Pennsylvania

ALTHOUGH improved roentgenographic technique and an impressive accumulation of medical literature have established the clinical significance of diverticula of the gastrointestinal tract, those of the stomach and duodenum remain relatively rare surgical entities. However in a period of $1\frac{1}{2}$ years in a Naval Hospital, 5 such cases have been encountered: 2 in the cardiac portion of the stomach and 3 in the third portion of the duodenum. All were diagnosed preoperatively and all patients have been treated surgically. It is our purpose in presenting these cases to summarize briefly the literature, to state our opinion that the symptoms of diverticula can be entirely relieved by the operation of inversion of the sac without excision, a procedure which has proved successful in our hands and which appeals to us as the safest of all surgical methods, and to consider in some detail several technical features which we have found helpful in its employment.

INCIDENCE

The incidence of diverticula of the alimentary tract cannot be determined, for most of them remain asymptomatic throughout life (15). However Babcock states that duodenal diverticula are found in 2 per cent of bodies, while Finney gives the frequency as between 1 and $1\frac{1}{2}$ per cent of adults. Lockwood found them in 1.7 per cent of routine gastrointestinal roentgenologic examinations. An incidence of 2.2 per cent was disclosed by Nagel in over 900 autopsies. Warren and Emery report an incidence of 2.3 per cent of patients showing roentgen evidence of gastrointestinal disease. That these figures may be too conservative is suggested by the work of Ackerman who by packing the duodena of cadavers with plaster of paris, demonstrated diverticula in 11 of 50

subjects. However Edwards (11) emphasizes that experiments on the dead intestine are entirely without value pointing out that the strength of the bowel depends upon the strength of its muscular coat and that the strength of muscle lies in its power to contract.

The stomach is infrequently the site of diverticula. Bockus states that over 150 cases have been reported, although in some of these the diagnosis was not established beyond question. Four gastric diverticula were encountered in 3,662 routine autopsies, as reported by Rivers, Stevens, and Kirklin. Shiffert stated they were observed in 0.65 per cent of 74 routine roentgenologic examinations of the stomach. Ten diverticula were removed in 11,234 exploratory operations on the stomach at the Mayo Clinic, according to Schmidt and Walters. Cunha encountered 15 cases of diverticula in the upper end of the stomach in 1 year, a fact indicating that their occurrence may not be too rare.

AGE AND SEX

Most patients having known diverticula are between 50 and 70 years of age. The youngest of Finney's patients was 47, the oldest 78; the average for the group was 63.7 years. Edwards (11) gives 51.9 years as the average age of 25 patients studied by him. In Warren and Emery's series of 103 patients the average age was 58 years, ranging from 30 to 84 years. The literature indicates a slight predilection for the male sex.

ETIOLOGY

Attempts to classify gastrointestinal diverticula have led to the designations true and false, congenital and acquired, primary and secondary, and pulsion and traction. True diverticula are composed of all mural elements, while one or more layers are absent in

the false variety. Congenital types result, by definition from anomalies of development and, according to Keith in many diverticula of the stomach. The age at which most diverticula become manifest favors their classification as acquired although it cannot be denied that an inherent weakness may be the underlying factor in such cases. Edwards (8) has identified this inherent weakness with the amuscular intervals in the bowel wall through which blood vessels pass. Intraluminal tension (pulsion) is of undoubted importance in the development of acquired diverticula and chronic cough constipation vomiting and labor are said to be factors in the genesis of lesions of this type. The so-called traction diverticulum results from adhesions secondary to ulcers and other inflammatory reactions of which the commoner examples are found in the bladder or stomach and pancreas and in the colon.

commonly in or close to the mesenteric border. Edwards (8, 9) on the basis of studies on specimens removed at autopsies and operations emphasized the constancy with which diverticula are associated with blood vessels. According to him the mesenteric arterioles bifurcate as they approach the bowel, the branches piercing both muscular coats a short distance from the mesenteric line. The amuscular interval through which the vessels pass has been designated by Edwards as a *locus minoris resistentiae*. These areas of lesser resistance form the anatomical basis for outpouching or herniation of the mucosa. The precise rôle of intraluminal tension in the genesis of diverticula remains speculative.

Three duodenal diverticula operated on by us originated in the posterior wall, a position corresponding to the mesenteric line. The diverticula of the stomach were found on the posterior wall of the cardia near the lesser curvature. The sacs in each case were retroperitoneal and were devoid of muscular fibers the mucosa forming a delicate translucent wall. The diameter of the smallest was 18 millimeters while the largest measured 45 millimeters. Definite muscular rings were identified in the necks in all cases. In each instance a single prominent blood vessel was found crossing over the pouch. However exploration of this vessel disclosed the constant finding that, as the neck of the diverticulum was approached it diverged from the sac wall. The small interval thus formed between the blood vessel and the neck proper contained areolar tissue. We believe this anatomical feature to be an important consideration in the surgical management of diverticulum and reference to it will be made under "Treatment."

SYMPTOMS

It is probable that most diverticula remain symptomless, an opinion supported by the frequency with which they are found incidentally at autopsy. Of 57 cases of duodenal diverticula studied by Whipple not more than half gave symptoms. It is widely held that symptoms due to diverticula are vague and inconstant, and that they do not present a syndrome clear enough to be of aid in diagnosis (10, 12, 14, 18, 23, 28). Lahey cited accu-

ANATOMY

The frequency of occurrence of diverticula throughout the alimentary tract is said by Van Noort to be in the following order: (1) colon, (2) Meckel's, (3) duodenum, (4) pharynx and esophagus, (5) stomach, (6) jejunum and (7) ileum. Of those arising in the duodenum three fourths are found in the second portion (12). In 85 duodenal diverticula recorded by Edwards (9) none originated in the first portion, 65 were in the second portion and 20 sprang from the third portion. Fletcher and Castleden stated that diverticula never occur in the first portion of the duodenum, although Weintraub and Tuggle found them there in 17 per cent of their cases and Lust described 3 in that location in 1 patient. Warren and Emery's 103 duodenal diverticula were located as follows: in the first portion 7 per cent, second portion 65 per cent, third portion 15.5 per cent, multiple 6.8 per cent.

Although Rankin and Martin claimed that their experience intestinal diverticula are found most frequently opposite the border of mesentery or in the lateral wall, most authors are in agreement that they occur most

mulation of food within the sac and ulceration as the factors determining the symptoms of duodenal diverticulum.

Of the cases treated by us 3 described their distress as sensations of pressure, tension or fullness. Another complained of moderately sharp pain. The site of distress or pain bore no specific relation to the site of the lesion. Thus, discomfort in the 3 duodenal cases was in the left epigastrium, the midepigastrium and the right umbilical region. One patient with diverticulum of the stomach complained of pain in the midepigastric area. In 2 discomfort usually followed ingestion of a large meal while 1 denied any relation between food and distress. One patient (Case 3) was able to obtain relief by eating or by taking baking soda. The only feature common to all of our patients was the intermittent character of their discomfort. It appears that the symptoms caused by diverticula of the proximal gastrointestinal tract are not specific, that they share features of other and more frequent pathologic states and that they are of value only insofar as they call for further diagnostic efforts.

DIAGNOSIS

The only reliable method of establishing the presence of a diverticulum of the gastrointestinal tract lies in x-ray examination. Photo-fluoroscopic and roentgenographic demonstration of a paraluminal sacculus following the administration of barium affords the diagnosis. Pendergrass advised taking a plain film of the abdomen prior to the ingestion of barium in order to differentiate fecaliths and calcified nodes. The diagnostic observations of Costello with reference to lesions of the duodenum include (1) roundness and smoothness in outline of the diverticulum (2) a connection between diverticulum and lumen demonstrated by emptying the sac by manipulation (palpation) and (3) retention of barium in the sac for periods up to several days. Barium filled pockets in relation to the duodenum which *per se* show peristalsis which empty with the duodenum and which are shallow and wide-mouthed, are apt to be secondary to primary ulcer, the so-called ulcer diverticulum (11). Examination should be made with the patient

in the upright, prone, lateral, and oblique positions. Efforts to fill sacs in which drainage is dependent may call for the Trendelenburg position or modification thereof. Guthrie and Brown suggested distending the duodenum with barium by blocking the duodenojejunal juncture with pressure by one hand, while the other hand manipulates the barium through the pylorus. The use of a duodenal tube in injecting barium, as recommended by Biedstein, does not appear to be general.

TREATMENT

While there is some disagreement as to the management of gastric and duodenal diverticula, the weight of opinion favors surgical treatment when symptoms persist or when the sac is large (3, 6, 10, 14, 19). Rankin and Martin prefer medical treatment, but state that surgical intervention seems warranted occasionally. Finney considered that duodenal diverticula should not alter life expectancy and concluded therefore, that very few of them were of surgical significance.

When abdominal symptoms are present in a patient with a demonstrable diverticulum and when no evidence of other disease of the digestive system can be found it is our practice to assume the existence of a relationship between symptoms and diverticulum and to advise operation. This is especially true if the sac is large and barium retention is noted by x-ray examination. Several procedures are available for the obliteration of diverticular sacs, invagination (inversion) of the pouch and simple closure of the mural muscular ring have the advantage of simplicity. Resection of the sac and neck or resection of the sac with inversion of the neck is frequently employed. In the face of contraindications to manipulation of the sac itself gastroenterostomy has occasionally been employed for relief of duodenal diverticulitis and segmental resection for lesions distal to the duodenum. Multiple diverticula may also demand bowel resection.

We prefer to rely on simple inversion of the sac for diverticula of the stomach and duodenum. This procedure is simple, a fact of first importance in attacking lesions of limited accessibility. The advantage of its asepticity is obvious. The hazard of obstruction following

Fig. 1 Diagrammatic view of operation for treatment of diverticulum by invagination. a, Exposure of the diverticulum on the upper surface of the third portion of the duodenum b diagrammatic cross section showing the

penetrating vessels as they appear on the diverticulum c, view of the diverticulum after ligation of the penetrating vessels d, closure of the muscular ring e, view showing complete suture.

invagination especially of the larger sacs is regarded as more academic than practical, an opinion supported by our experience.

OPERATIVE TECHNIQUE

On the evening before operation or early in the morning of operation a glass of bismuth mixture is given by mouth. This gives the diverticulum a white lining and aids materially in its identification at operation.

The incision for both gastric and duodenal diverticula is made in the midline, and the peritoneum is divided at the site indicated by the roentgen plate. Thus the retroperitoneal space is entered where the white wall of the diverticulum can be identified by pushing aside the loose fatty tissue. Most diverticula which show retention will be found to protrude through a small muscular ring which may be clearly identified by gentle dissection. Usually one or two small vessels are found to

pass from the outside of the muscle layer to the rising surface of the diverticulum. After they have been divided between fine silk ligatures the sac can be completely inverted with in the lumen of the gut and the muscular ring closed with fine silk sutures. The operation is completed by approximating the divided peritoneal layer (Fig. 1).

In the postoperative care food and fluids by mouth are withheld for 3 to 4 days to permit the effects of the operative trauma to subside.

CASE 1 F B M a 43 year old boatswain in the United States Navy was admitted to the hospital on April 4, 1944 complaining of intermittent abdominal pain. Upper abdominal distress described as a feeling of tension often amounting to pain, had begun in 1934. The symptoms were referred to a point just to the right of the umbilicus, they developed shortly after meals particularly those consisting of fried or highly seasoned foods and fats. Vomiting was infrequent. The bowels had always been normal. A diagnosis of chronic cholecystitis had been made originally and gall bladder drainage had

been employed many times. Later, the patient was told that he had an ulcer. Recently when duty in Africa had made it impossible for him to adhere to his restricted diet the abdominal symptoms had become aggravated. X-ray studies of the gastrointestinal tract were said to have shown an intestinal diverticulum. The past history was not noteworthy. The patient's father had died of cancer. Physical examination showed the patient to be a robust looking, white male in early middle life. Findings at general examination were not remarkable except in the abdomen. There was no distention or free fluid. The liver and spleen were not felt. There was no palpable mass. A circumscribed area of moderate tenderness to deep pressure was present, centering at a point 3 centimeters to the right of the umbilicus. Rebound tenderness was not present nor was the right hypochoadrum tender. Laboratory findings were normal. Repeated examinations of the stools for occult blood and bile were negative. A gastrointestinal x-ray series disclosed no abnormality in the esophagus, stomach or duodenal cap. However a large diverticulum was present, arising from the duodenum near the duodenojejunal juncture (Fig. 2). Films made 2 and 4 hours after the ingestion of barium showed considerable retention of the medium in the diverticulum. The 24 hour film showed none. On May 3, 1944, laparotomy was performed through an upper abdominal midline incision under continuous spinal metyrcaine anesthesia. Omental adhesions to the anterior parietal peritoneum were separated. The ligament of Treitz was divided and the incision was carried somewhat to the right opening thereby the posterior parietal peritoneum and exposing the terminal duodenum. The diverticulum measuring 3.5 by 3 by 1.5 centimeters was found arising from the upper mesial and posterior surface of the duodenum, 4 centimeters proximal to the duodenojejunal fold. The neck was small and communicated with the lumen of the gut through a muscular ring 2 millimeters in diameter. It was inverted into the duodenum, and the hiatus in the muscularis was closed over it with interrupted sutures of chromic catgut No. 0. The posterior peritoneum was sutured over the duodenum, and Treitz' ligament was reconstructed. The wound was closed in layers, following the instillation of 25 cubic centimeters of a 20 per cent suspension of microcrystalline sulfathiazole into the retroperitoneal pocket. Healing was complicated by the formation of a subcutaneous hematoma, evacuated on the seventh postoperative day and by a small disruption of the wound on the tenth day permitting evisceration of a walnut-sized mass of omentum. This was repaired at once. The serum protein on this day was 6.8 milligrams per cent. Infection of the abdominal wound (*Bacillus coli*) developed 13 days following the secondary closure and was quickly controlled by 460,000 units of penicillin. This series of complications forced the intermittent use of gastric (Wangenstein) suction and parenteral fluids until the 32nd postoperative day when the tube was removed and soft diet permitted. Full diet was given

after the 37th day. Gastrointestinal x-ray series June 11, 1944, disclosed no abnormality in the duodenum (Fig. 3). The patient remained free from gastrointestinal symptoms following the operation. He was discharged from the hospital on July 6, 1944.

CASE 2: J. A. C., a 43 year old specialist, in class. In the United States Naval Reserve, was admitted to the hospital May 29, 1944. His complaint of pain in the left upper abdomen was of 2 years' duration. The pain was intermittent, being most troublesome after heavy meals, and was described as feeling as though "a pocket of gas was pressing on the heart." It had never been severe, was well localized in the left epigastrium and had no relationship to the type of food eaten. The sensation of pressure was accompanied by mild shortness of breath. There had been no nausea or vomiting. One year previously, the patient had had a similar single attack, lasting a few days and abating without treatment. His appetite had continued good and he had not lost weight. The bowels were somewhat "irregular." Appendectomy had been performed in 1932. The family history was not relevant. Physical examination showed no abnormal findings, except in the abdomen. An oblique, healed scar was present in the right lower quadrant. No distension or fluid was noted. Deep palpation elicited mild tenderness centering at a point 3 centimeters below the costal border on the left parasternal line. Rebound tenderness was not present. Laboratory findings were normal. Examination of the stools disclosed no occult blood, parasites, or occult blood. Gastrointestinal x-ray series revealed a large diverticulum arising from the upper surface of the transverse duodenum in its distal third (Fig. 3). The diverticulum remained filled with barium at the end of 4 hours, but there was otherwise normal progression of the motor and Barium enema disclosed several bud-like diverticula in the transverse, descending, and sigmoid colon. Laparotomy under continuous spinal metyrcaine anesthesia, was performed on June 23, 1944. The abdomen was opened through an upper midline incision. A diverticulum 5 centimeters in diameter was found springing from the duodenum at the ligament of Treitz. The pouch was isolated and amputated through a narrow hiatus in the duodenal muscularis. The muscle opening was closed with a continuous seromuscular suture of chromic catgut No. 0, reinforced with nylon. Five grams of microcrystalline sulfathiazole suspension were placed in the peritoneal cavity. The abdomen was closed in layers with steel alloy wire. Continuous Wangenstein drainage was employed for 48 hours postoperatively during which time the patient was supported with parenteral fluids. On the second postoperative day liquids were given by mouth. Soft diet was ordered on the fourth day and a full diet was permitted after the ninth day. There were no complaints referable to the alimentary tract following the operation. Healing was normal. The patient was allowed out of bed on the sixth postoperative day and was discharged to duty 1 month after operation. Gastro-

Fig. 2 a, left, Preoperative x ray film of Case 1, b postoperative x ray film 6 weeks after invagination of the diverticulum (official U S Naval photograph)

Fig. 3 a, left, Preoperative x-ray film showing diverticulum of the third portion of the duodenum b postoperative x ray film about 15 days following invagination of the diverticulum (official U S Naval photograph)

intestinal x ray examination on July 6 1944 showed no evidence of diverticulum in the duodenum (Fig 3) The progression time of the barium was found to be normal

CASE 3 W A S aged 38 years a seaman first class in the United States Naval Reserve was admitted to the hospital on April 18 1945 with the complaint of upper abdominal pain of 1 year's duration For 6 or 7 years the patient had had frequent attacks of indigestion the features of which were a feeling of fullness in the stomach heartburn and belching One year previously an especially severe attack had been experienced during which the patient suffered pain in the upper abdomen felt nauseated and vomited Similar and even more aggravated episodes had followed at shortening intervals These were not associated with the ingestion of food

rather they were somewhat relieved by eating and taking soda The midepigastrium was indicated as the site of discomfort The bowels were sluggish moving every 2 or 3 days There had been no weight loss The patient smoked 20 cigarettes per day and drank whiskey moderately His previous medical history was not significant in any particular His father had had stomach trouble for years Physical examination showed a normally developed middle aged white male who presented no abnormality in any particular except in the abdomen Moderate tenderness to deep pressure was present in the epigastrium and was greatest at a point halfway between the umbilicus and the ensiform process The iliac colon was also slightly tender No organs or masses were palpable The laboratory findings were normal Repeated stool specimens contained no oc

Fig. 4. a, left, Preoperative x-ray film showing diverticulum of the third portion of the duodenum. b, postoperative x-ray film 3 weeks after invagination of the duodenum (official U. S. Naval photograph)

cult blood. Gastric analysis disclosed normal values for acid and contained no blood. Lactic acid Roentgenograms of the gastrointestinal tract showed no defect in the esophagus or stomach. At the juncture of the second and third portions of the duodenum there was a large diverticulum measuring 5 centimeters in its widest diameter (Fig. 4). At the end of 4 hours the stomach was empty but a small residue was seen in the diverticulum, the neck of which appeared directed caudad. Laparotomy through an upper abdominal midline incision under continuous spinal pontocaine anesthesia was performed on May 6, 1945. The stomach and gall bladder were normal. The distal duodenum was visualized by incising the posterior peritoneum and a large diverticulum was exposed arising from the superior border of the duodenum. Ligation of a single large vessel which coursed over the sac permitted dissection and mobilization of the entire pouch. This was found to communicate with the lumen of the bowel through a well demarcated muscular ring in the bowel wall. The diverticular sac was inverted into the gut through this muscular ring which was closed by means of interrupted nylon sutures. The posterior peritoneum was reconstructed and the abdominal parietal wound was closed in layers with steel alloy wire. Liquid diet was permitted sparingly immediately after operation. Soft food was begun on the fourth day and a full diet on the seventh postoperative day. The patient was allowed out of bed on the fourth postoperative day. The wound healed perfectly. There were no complaints referable to the gastrointestinal tract following the operation. Gastrointestinal x-ray series on June 7, 1945, revealed no evidence of the previously noted diverticulum (Fig. 4). At the end of 4 hours the stomach was empty and the head of the barium meal was in the cecum. The patient was discharged from the hospital to duty 4 weeks after operation.

CASE 4. F. J. D., a 27-year-old veteran, was admitted to the hospital October 16, 1944, with the complaint of pain in the upper abdomen. The pain, of 2 years' duration, was dull, radiated to the upper right quadrant and was intermittent. For many months, it had awakened him each morning. It had no relationship to meals or to the type of food eaten, and was not relieved by alkalis. Vomiting was not a complaint. The patient had lost 90 pounds during the previous 30 months, although his appetite remained good. Bowels were normal. He smoked 20 cigarettes per day but did not use alcohol in any form. The patient had received a medical discharge from the Army in October 1943 because of the diagnosis of diverticulitis. Appendectomy was performed in May 1944. The family history was not pertinent. Physical examination showed the patient to be a tall, spare young adult male, not appearing ill. His weight was 150 pounds. The particulars of the examination were essentially normal with the exception of the abdomen. No distension or fluid was present. The liver and spleen were not felt and no masses were palpated. Moderate tenderness resulted from deep pressure in the epigastrium, the point of greatest discomfort being just to the right of the midline 3-5 centimeters below the costal arch. Laboratory findings were normal. Repeated examinations of the stools were negative for ova, parasites, and occult blood. Gastric analysis disclosed normal values for free and total acid. Gall bladder visualization studies showed normal filling and emptying with no evidence of calculus. Gastrointestinal x-ray series revealed a diverticulum measuring 2 by 1.5 by 1 centimeter arising from the posterior wall of the stomach near the lesser curvature just below the esophageal hiatus and connected to the stomach by a narrow neck (Fig. 5). The barium remained in the diverticulum for 24 hours (Fig. 5). On November 13, 1944, laparotomy was performed under continuous

Fig. 5 a, Diverticulum near cardiac orifice of the stomach, b, appearance of diverticulum 4 hours after barium meal, c, operative exposure of diverticulum showing ligated vessels, d, postoperative x ray film 32 days following invagination of the diverticulum (official U S Naval photograph)

spinal pontocaine anesthesia employing an upper midline incision. The lesser bursa was entered through the gastrohepatic omentum and the posterior gastric wall was mobilized. The diverticulum, about the size of a maraschino cherry was identified on the posteromesal wall of the stomach directly beneath the cardiac orifice. The neck was 8 millimeters in diameter. A single artery was seen coursing over the pouch (Fig. 5). The sac was inverted through the neck i.e. through the defect in the gastric muscularis, and the muscular ring closed by means of a continuous Lembert suture of chromic catgut No. 0. Five grams of microcrystalline sulfathiazole suspension were placed in the lesser cavity and the gastrohepatic ligament was closed. The abdominal incision was closed in layers with steel alloy wire. Nothing was given by mouth until the third postoperative day when liquid diet was permitted. Soft food was ordered on the fifth day and full diet on the seventh. The patient was ambulatory following the sixth postoperative day. Healing of the wound was uncomplicated and the patient was discharged from the hospital without complaints 26 days after operation. Gastrointestinal x ray series on December 5, 1944 disclosed no defect at the diverticulum site.

CASE 5 C S W a 25 year old seaman was admitted to the hospital on May 10, 1945 complaining of epigastric pain and frequency of bowel move-

ments. The epigastric pain appeared after eating and was not relieved by soda or food. The bowel movements numbered 3 to 5 daily and were often liquid and associated with crampy abdominal pain that appeared to be distinct from the epigastric distress. The patient had lost 18 pounds in the preceding 2 months aboard ship. Physical examination showed a thin young male with definite local tenderness on deep pressure in the upper epigastrium and some tenderness over the sigmoid area. Gastric analysis was normal. There was a slight anemia. An x ray examination showed a gastric diverticulum arising near the esophagogastric junction which seemed to project posteriorly and to the left. The diverticulum was still visible at the end of 4 hours. A barium enema showed the loss of haustrations typical of a colitis. Operation on May 21, 1945 under serial spinal anesthesia revealed the diverticulum as shown by x ray examination. It was treated by invagination and closure of the muscular ring with interrupted silk sutures. The patient made an uneventful recovery from operation and an x ray examination showed no evidence of the previously present diverticulum. He was relieved of his epigastric distress but his symptoms of colitis persisted.

These 5 patients with gastric and duodenal diverticula presented vague upper abdominal

symptoms which had persisted for some time in spite of treatment. Usually the treatment had been given for one of the more common upper abdominal lesions, ulcer or gall bladder disease. A finding common to the group was the retention of radiopaque material in the diverticulum. This condition was shown to be due to a sac with a very small neck and it is probable that the symptoms arose from recurring distension of the sac. Repair of the diverticulum by invagination of the thin sac of mucosa produced a relief of symptoms. The invaginated mucosa apparently atrophies or shrinks up to resume a normal position as shown by the normal appearance of the post-operative roentgenograms.

SUMMARY

1. A brief review of the incidence, etiology, symptoms, and diagnosis of diverticula of the upper stomach and duodenum is given.

2. A technique of treatment by invagination of the diverticulum and suture of the muscular ring is described.

3. Five cases are presented in which the patients were treated by this method with relief of symptoms due to the diverticula in all cases.

GROWTH OF HUMAN TROPHOBLAST IN EYE OF RABBIT ITS RELATIONSHIP TO THE ORIGIN OF CANCER

A Preliminary Report

CHARLES GURCHOT Ph D ERNST T KREBS Jr MA. and
ERNST T KREBS M D San Francisco, California

A RELATIONSHIP between the pregnancy trophoblast and cancer has long been suspected (10 14 81 94). It was particularly well explored by John Beard (10 11, 12, 13) on the basis of extensive embryological and zoological studies (5 6 7 8 9). It was further implied in the later experimental work of Loeb (55, 56 57) Brachet, Maximov Blumenthal and Auler and Kido. It is the purpose of this communication further to clarify this relationship particularly in the light of vertebrate metagenesis.

Experiments to be described are the first of a series of transplantations of human placental material in the anterior chamber of the eye of the rabbit. They constitute confirmation of similar experiments performed by Kido and serve to illustrate *in vivo* the results obtained by Maximov with growth of rabbit conceptus in tissue culture.

Our results indicate that heterologous trophoblast grows easily and promptly in the anterior chamber in a manner analogous to malignant tumors.

EXPERIMENTAL MATERIAL AND PROCEDURE

Tissue explants obtained from normal human placentae aged 2 5 7 months and at term were placed in the eyes of 8 rabbits including two serial transfers. A total of 27 implants were made in 16 eyes through incisions performed at the corneal scleral margin under local anesthesia produced by instillation with 5 per cent cocaine hydrochloride. Explants were obtained after dissecting off the maternal portion from within and just below the spongy layer of the placenta. A section of the 5 months' placenta is shown in Figure 1. Of

the 8 rabbits which were all less than 4 months old and obtained from widely separate sources 6 were virgin albino females 1 was a young albino male and 1 a black young male. The females were kept in two large cages the males each in a separate cage and all were kept in a quiet dark room. The use of different placentae in animals of unlike strains insured against the probability that results might be due to virus infection. Corneal incisions were well healed after several days. A latent period of from 2 to 4 days preceded evidence of growth. All implants were examined every few days with a binocular magnifier ($\times 10$).

Rabbit 1 Small albino virgin female (circa 1 5 kgm.) inoculated with 5 months' placental tissue.

Right eye—1 implant 1 by 1 millimeter placed 4 millimeters below corneal scleral junction. Left eye—1 implant 1 by 1 millimeter close to junction.

7 days Right eye—Implant 2 by 2 millimeters. Eye hyperemic around edges. Incision site slightly raised. Implant pale yellow and translucent. Left eye—Implant not well demarcated. Zone of diffuse growth 2 by 3 millimeters. Cornea vascularized between implant and sclera.

26 days Right eye—Implant 2 by 3 millimeters. Appears to have moved closer to sclera. Left eye—Implant 4 by 4 millimeters and round. Well demarcated yellowish, no diffuse zone. Upper border of vascularized implant attached at corneal-scleral junction.

80 days Right eye—Implant has all but disappeared. Very small mass remaining at corneal scleral margin. Left eye—Implant almost circular yellowish with a more diffuse but well demarcated crescentic area extending beyond the denser yellowish mass. Appears to be growing within or attached to the cornea and is well vascularized. Eye slightly opalescent with granular area below entire implant but otherwise normal in appearance. Little change in size.

Rabbit 2 Medium size (circa 2 kgm.) albino virgin female inoculated with 5 months' placental tissue.

Right eye—Three implants measuring about 1 by 1 millimeter were placed 2 to 3 millimeters from

31 Ernst T. Krebs, Jr. is formally connected with the Division of Anatomy, University of California Medical School.

Fig. 1. Ripening follicle in left ovary of Rabbit 2. It is seen in the middle of the same ovary shown in Figure 2. X65

junction at 2, 6 and 8 o'clock. Left eye—One implant 2 by 1 millimeter at junction and at 11 o'clock second implant 1 by 1 millimeter at 3 o'clock 2 millimeters away from junction.

7 days. Right eye—Densely clouded and glaucomatous but implants visible. Only 12 o'clock implant growing and is now 2.5 by 2 millimeters. Situated 2 millimeters below junction it appears very close to the iris. Left eye—11 o'clock implant pale yellow and lobulated. No diffuse zone in glaucoma size 1.5 by 2 millimeters. Three o'clock implant 2 by 1 millimeter pale pink not attached.

18 days. Right eye—No further growth of 12 o'clock implant no change in appearance. When this growth was sectioned it was found to constitute a very thickened portion of the iris outside of which no discrete mass was found. Since this implant was seen from the beginning at a point near the iris and appeared later to have grown very close to the invasion of the iris may have occurred during observations. Histological section of the remaining right eye implant (Figs. 5, 7, 8 and 9) shows the presence of giant cells and syncytial masses strongly

Fig. 3. Ripening follicle in ovary of Friedman doe injected with urine obtained from black male Rabbit 3. X65

Fig. 2. Left ovary of Rabbit 2 showing cystic development of follicles. X10.

suggestive of chorionic villi. The other two nipples had apparently been absorbed. Left eye—11 o'clock implant 2 by 3 millimeters fixed to cornea and was herniated at site of growth and appeared like a small boil (Fig. 4a). Three o'clock growth unchanged (Fig. 4b). Eye glaucomatous but clear.

This animal was killed after the eyes were removed under general anesthesia. When the herniated implant of the left eye was accidentally touched with forceps it broke open at one point. The intraocular pressure produced a fine stream of aqueous humor 18 inches high.

When the abdomen was opened the uterus was found definitely hyperemic. The ovaries showed no gross changes. The eyes, uterus, and ovaries were removed and fixed in Bouin's fluid, sectioned, and stained. The stained section of the uterus shows proliferation of the labyrinthine glands brought about by steroid hormones, while the ovaries show follicle ripening and a beginning of the formation of follicular cysts (Figs. 1 and 2).

The stained section of the 11 o'clock implant of the left eye is shown in Figure 4a. There is marked distortion of the iris and bridges connecting the iris with a hypertrophied ciliary body. The herniation was followed also by marked distortion of the iris, with

Fig. 4. Section of anterior chamber of Rabbit 2. Left of herniation at site of degenerating implant. It may indicate that extrusion of iris is in part due to erosion by trophoblast whose morphology may be obscured by osmotic response of iris and ciliary body. Left eye. X100.

Fig. 5. Inset. Giant cell in Figure 7 photographed through a dark green filter. The nuclei arranged at the periphery give this cell the appearance of chorionic villus. X200.

Fig 6. Section of normal 5 months placenta. Compare syncytium with that to be seen in both Figures 8 and 9. $\times 200$.

was pushed up against the cornea. Part b in Figure 4 shows the second implant to be degenerating.

Rabbit 3. Medium size black young male (circa 2 kgm.) inoculated with 5 months placental tissue.

Right eye—Implant 2 by 1 millimeter near corneal scleral margin. **Left eye**—Two implants one near margin 2 by 2 millimeters the other 3 by 2 millimeters was pushed to the bottom of the anterior chamber.

7 days. **Right eye**—3 by 1.5 millimeters pale yellow and well demarcated. Surrounded by clear zone less than 1 millimeter wide. Beyond zone a dense white outer margin was seen about 1 millimeter wide. Very small knob on lower margin of implant. Slightly diffuse zone extending to 3 millimeters around growth. Incision site elevated. Sclera hyperemic for a distance of 8 millimeters on each side. Implant appears attached near incision site. **Left eye**—Implant near junction 3 by 3 millimeters. Bottom implant 2 by 5 millimeters. Chamber slightly cloudy and

Fig 7. Section of ins from right eye of Rabbit 2. Giant cells, whorls, and syncytial masses suggest chorionic villi. $\times 200$. Photographed with light green filter.

glaucomatous. Sclera markedly hyperemic near first implant close to incision site. This implant has a small knob protruding from lower border. It is well demarcated and yellowish. Lower implant has ragged edges and is rectangular with well defined but diffuse brush like extensions from each end. They have the appearance of strands characteristic of sarcomas cultured *in vitro*. The ragged edges of the growth examined through the cornea with a Greenough type binocular microscope ($\times 40$) showed growing sheets of tissue which appeared like a surface of wave like crests finely granular with a beautiful opalescent sheen showing well against the black background. In contrast to the brush like extensions on the ends of the growth the sheet-like proliferation from the same implant is reminiscent of carcinoma.

16 days. **Right eye**—Implant 3 by 6 millimeters. Oval in shape and yellowish with well demarcated crescentic diffuse extension on the left side toward

Fig 8. Higher magnification of part B outlined in Figure 7. Photographed with dark green filter. The rows of nuclei in the syncytial strands and whorls can be readily seen. $\times 300$.

Fig 9. Higher magnification of part C outlined in Figure 7. Photographed with dark green filter. The giant cell mass in the center appears to be arising out of a chorionic villus. $\times 300$.

Germ cell evocation

Fig. 2. Diagrammatic chart of germ cell development. Normal evocation on the left. Evocation culminating in cancer is shown on the right. The dotted lines indicate phases of simple mitotic multiplication and only one of the resulting cells is figured to indicate subsequent development. Each represents the fate of that single cell.

inner canthus. Left eye—Top implant 3 by 5 millimeters. Bottom implant circa 2 by 5 millimeters. Top implant appears attached to the cornea and sclera. No cloudiness. Growth vascularized and spreading down in the direction of the inner canthus where a diffuse zone is visible about 3 by 3 millimeters. Bottom implant also yellow and vascularized. Brush end have now almost disappeared but implant is slightly larger.

Fig. 1. Left. Right eye of Rabbit 4 showing vascularized

Fig. 2. Center. Right eye of Rabbit 4a bearing

Fig. 3. Right. Left eye of Rabbit 4a bearing serial transplant obtained from right eye of Rabbit 4.

30 days. Right eye—Implant 4 by 6 millimeters. Vascular. Nictitating membrane appears large, normal in color. Left eye—Upper implant 4 by 3 millimeters vascularized. Bottom implant 3 by 2 millimeters, crescent shaped. Eye slightly glaucous and clear. The urine from this male rabbit was collected on the twenty first day and injected into a Friedman doe. At the end of 48 hours the reaction was positive for the presence of chorionic gonadotropin although as a pregnancy test it could have been rated as doubtful since there were no blood points observed instead of frankly hemolytic follicles. However we are here dealing with the urine of a male rabbit rather than from that of a pregnant woman. The ovaries were removed and prepared for histologic examination. A section is shown in Figure 3.

Rabbit 4. Large albino male (circa 3 kgm) mated with 5 months placental tissue.

Right eye—One implant 1 by 1 millimeter at corneal-scleral junction. Left eye—Three implants, all 1 by 1 millimeter. One near junction at 10 o'clock, two implants at 4 o'clock placed between pupil and junction.

7 days. Right eye—Implant now 2 by 2 millimeters. No glaucoma. No inflammation. Eye clear. Left eye—Very cloudy containing an irregular broken ring of yellowish implants in and below pupil. Glaucomatous. No apparent inflammation.

26 days. Right eye—Well vascularized implant 5 by 4 millimeters. Eye glaucous and clear. Left eye—Cloudy difficult to observe. Animal is apparently distressed. Very restless and moaning head to one side. Occasionally squeals as if in pain. Implant appears as large irregular broken mass situated mostly near bottom of chamber. No apparent inflammation.

30 days. Right eye photographed (Fig. 1). Left eye too cloudy. Not photographed. Right eye implant 6 by 4 millimeters. On the fifty-first day animal anesthetized with sodium pentobarbital and left eye was removed, fixed in Bouin's fluid, sectioned and stained. Implant in right eye was firmly attached to the cornea of which a piece 7 by 5 millimeters was excised. Two fragments were cut from this piece and transplanted along with the attached cornea from which implant could not be separated.

into a small, young albino female virgin rabbit (Rabbit 4a). The testes from the host rabbit were removed, fixed, sectioned and stained. There was indication of some inhibition of spermiogenesis. A histological section of the left eye shows the iris and ciliary bodies to have hypertrophied markedly and grown entirely across the anterior chamber. Both iris and ciliary bodies are connected by many long bridges. Although the normal rabbit eye may show a remarkably large ciliary body and outgrowths of loose vascular tissue from the iris the eye of Rabbit 4 represented a very marked departure from the normal and after 60 days there were no signs of inflammation.

Rabbit 4a. Young albino virgin female (circa 1.5 kgm.) implanted with corneal fragments obtained from Rabbit 4.

Right eye—Implant 2 by 2 millimeters including cornea. **Left eye**—Implant 1 by 3 millimeters including cornea. Within 24 hours growth was apparent. Within 3 days right eye transplant measured 3 by 4 millimeters. Left eye implant 2 by 3 millimeters. Right eye markedly inflamed (Fig. 12). Left eye normal (Fig. 13).

30 days Right eye—Implant growing attached to the cornea. Size 2 by 8 millimeters, vascularized. **Left eye**—Implant now 2 by 5 millimeters. At first irregular it now appears more like the right eye implant.

Rabbit 5. Small albino virgin female (circa 1.5 kgm.) inoculated with tissue from a 7 months' placenta.

Right and left eye—One implant in each 2 by 1 millimeter near corneal-scleral junction. Grew slowly after about 4 days.

30 days Both implants now 2 by 2 millimeters.

68 days Both implants 1 by 1 millimeter. Definite regression has occurred after a very slow initial growth.

Rabbit 6. Medium size albino virgin female (circa 2 kgm.) inoculated with tissue from a term placenta. Organ was soft, spongy and very bloody.

Right eye—Two implants 2 by 2 millimeters. One in area of pupil the other at the corneal-scleral junction. There was a latent period of growth of about 12 days. **Left eye**—Three implants all near pupil around the edge. Size 2 by 2 millimeters.

27 days Right eye—Pupil implant almost entirely absorbed. Implant at junction well demarcated, yellow. Size 2 by 5 millimeters. Left eye—All 3 implants absorbed.

32 days Right eye—Implant 3 by 5 millimeters. Slightly vascularized.¹

Rabbit 7. Small albino virgin female (circa 1.5 kgm.) inoculated with 2 months' placental tissue.

Right eye—Two implants 2 by 2 millimeters placed at 4 millimeters below corneal-scleral junction. **Left eye**—Two extremely small implants placed 4 millimeters below junction at 12 o'clock.

¹The presence of syncytial steroids was verified in the implants of this animal by histochemical methods. Private communication from G. B. Winkler.

All 4 implants grew only slightly. After 38 days 2 implants were left measuring about 1 by 1 millimeter. They appeared not to be growing.

The experiments herein described indicate that normal human pregnancy trophoblast, when grown in the anterior chamber of the eyes of rabbits, behaves like a malignant tumor grown in a similar medium. This raises the question of how closely related these two tissues are. Our experiments, as well as a great many other data, suggest that all malignant tumors regardless of their protean character, are fundamentally trophoblastic. Admittedly if this is true there are many things to be explained and in the case of most tumors the relationship between pregnancy and cancer trophoblast can only be a subtle one. We know that trophoblast *per se* can be violently malignant, indeed its malignancy can be of a degree not exceeded by any known tumor. That trophoblast, like other tissues may be capable of undergoing malignant degeneration cannot be seriously considered here because no one knows what malignant degeneration is. Moreover, it is particularly because of the need to explain 'malignant degeneration' that the relationship between trophoblast and cancer is being examined. Also if we keep in mind that growth of the implanted heterologous trophoblast in the anterior chamber was observable grossly only a few days after inoculation it is very doubtful if it can be said to have undergone 'malignant degeneration'.

The analogous behavior of trophoblast and malignant tumor implants is consistent with the generally accepted observation that chorionepithelioma appears as a simple overgrowth of normal trophoblast cells (22).

If cancer is fundamentally trophoblastic it can only be germinal in origin. It is well to point out the semantic limitation of the term cancer as applied to a complex structure whose malignant properties are attributable to one component only, for if cancer is trophoblastic it is, like the chorion a dual tissue unless it happens to be anaplastic. In this case it might qualify as a polymorphic manifestation of chorionepithelioma. The nontrophoblastic component of the chorion is embryonic where as the nontrophoblastic component of cancer

is somatic. In either case the embryonic or somatic components tend to limit the relative growth of the trophoblast. Indeed the growth of the former would appear to be stimulated by trophoblast. This is particularly suggested by the marked growth of embryonic mesenchyme pushing the pregnancy trophoblast at first relatively smooth into the multibranched chorion frondosum eventually. Thus the relative development of each tissue gives the combination its own particular architecture.

Because of its antagonism to somatic tissues (embryonic as well as adult) trophoblast can not be described as embryonic. To the contrary trophoblast precedes the embryo in development and represents the asexual or pre-embryonic generation. Better known in the invertebrates the asexual generation is generally recognizable as the trochophore or some modification of it, the morphology of which is practically identical through six different phyla.

Both the asexual (trophoblast) and the embryonic (sexual) generations stem from a single origin—a diploid totipotent cell (germ cell). Germ cells are totipotent because they can give rise to complete embryos. If a diploid totipotent cell undergoes meiosis a gamete-like cell is formed. If the diploid totipotent cell proliferates as such (without meiosis) more germ cells are formed—one or more of which may eventually proceed through differentiation to definitive embryogenesis.

Diploid totipotent cells have three possible fates. They may (1) proliferate through simple mitosis and produce more totipotent cells or (2) proliferate through meiosis and produce gamete-like cells or (3) proliferate through differentiation and produce embryos.

During the early cleavage of activated gamete-like cells some of the daughter cells are trophoblast and the remainder are totipotent cells. Thus in 1 all resulting cells are totipotent. As a result of 2 and after activation only some of the cells are totipotent. In 3 all resulting cells lose their totipotency but all cells do not *totally* lose their potencies.

A gamete-like cell, after activation or fertilization divides to produce trophoblast cells (asexual generation) and embryo-forming cells. The latter represent totipotent cells, one or more of which differentiates in the process of

definitive embryogenesis while the remaining diploid totipotent cells, the total potency of which is reserved from early cleavage, comprise the germinal stream. During gestation the embryo is formed by the direct differentiation (without meiosis) of a totipotent or (germ cell) segregated from the trophoblast during very early cleavage. In mammalian eggs, as in the eggs of a number of lower forms the segregation most likely occurs at the very first cell division (75). So far as totipotency is concerned the germ cell *per se* can give rise to the sexual generation only. After meiosis, however, a resulting gamete-like cell can give rise during cleavage both to the trophoblast (asexual generation) and to embryo-forming diploid totipotent or germ cells (Fig. 10).

The two generations develop in autonomous of each other as reflected in their eventual mutual antagonism. The relationship between the asexual and sexual generations is the basis for metagenesis.

Metagenesis, sometimes referred to as alternations of generations, implies a discontinuity in the life-cycle whereby in animals the definitive sexual generation may be said to be preceded by a nonembryonic asexual generation. There may be overlapping and the discontinuity is not absolute. Hitherto regarded in the higher animals as a more or less academic concept, metagenesis assumes a fundamental importance with regard to the etiology of cancer.

Like other developmental phenomena cancer is the result of organizer action upon competent cells—specifically totipotent or totipotent cells (59-89). The conclusion that cancer cannot develop from cells of lower potency is based upon accepted morphogenetic principles (89-66). Organizer stimuli upon totipotent cells, as well as cells of lower potency possessing fewer competences, may be mediated by hormones, hydrocarbons or viruses. The diploid totipotent cells of higher animals are normally dispersed throughout the soma (sexual generation) (4, 11, 21, 61, 72, 74-84). This dispersion has substantial phylogenetic roots, since these cells are responsible for complete regeneration in lower forms (17). Their early separation from the trophoblast of the conceptus is apparent at the four-cell stage

in a number of mammals (49-85). From then on the trophoblast cells and the totipotent (embryo-forming) cells go their separate way, "the one can never become the other" (85).

The somatically dispersed totipotent cells, in contrast to embryonic somatic cells of lesser potency do not take part in repair processes and indeed are normally functionless in the higher chordates (45, 94). Their total potency or competence is reserved since early cleavage (78) and is not acquired from somatic cells (92) whose lower order potency or competence cannot give rise to cells of higher potency (2, 18, 32, 67). This principle of the irreversibility of potency has been well expressed in connection with evolution and is known as Dollo's dictum. It states that so far as animal structure is concerned evolution is irreversible, but regarding adaptation to a new environment simulating conditions which obtained in the past in another environment, evolution is reversible. In this case new organs may be developed from reserved *anlage* the new organs serving functions analogous to old organs which have disappeared never to return (29). This generalization applies with equal force to cellular development. Phylogenetically and ontogenetically cellular potencies once lost or expended can never be regained. This is not to be confused with the various possible fates of pluripotent cells which have a number of prospective potencies. For example undifferentiated mesenchymal cells may differentiate into hemocytoblasts, macrophages, primitive fibroblasts, osteoblasts, chondroblasts or several other forms. Some of these products of mesenchymal differentiation may likewise have a number of prospective potencies. Existing confusion in terminology may make it appear that certain differentiated cells may give rise to more primitive cells. But it was eventually verified that there is no going back on the scale of potencies (2). It is as impossible for totipotent cells, for example to arise from somatic cells as it would be for a neuron to form primitive ectoderm or for an erythroblast to form primitive mesenchyme. As for mutations, so far as they may be said to have any bearing on potency they can only be followed by an overall decrease rather than an increase as it is apparent on the evolution scale (18).

With respect to ontogenesis the concept of gene-mutations as they are known to occur would appear to be quite irrelevant.

From the number of somatically dispersed totipotent cells counted in 4-5 millimeter embryos (45) and in a number of elasmobranch embryos of various ages (7-8-9) it can be calculated that there are at least 3×10^4 totipotent cells—possibly more—dispersed in adult man an average of 2 for every cubic millimeter of tissue. This is after making allowance for 50 per cent degeneration and assuming that these cells continue to proliferate at the same rate as their surrounding cells, as they are known to do in embryos (8). These cells possess a competence for either trophogenesis or somatogenesis (embryogenesis) (Fig. 10). The latter occurs only by differentiation (without meiosis) of a germ cell and possibly only within a trophoblastic medium (decidua). Trophogenesis, on the other hand, can occur only after a germ cell or totipotent cell has undergone meiosis (heterotypic mitosis) resulting in a gamete or gamete-like cell which, now obliged to divide or perish, possesses an obligative competence for trophogenesis. The occurrence of teratomas in practically every part of the organism, as well as the occurrence of extragenital chorionepitheliomas in both sexes, is further evidence for the existence of somatically dispersed totipotent cells which although they usually remain functionless may unfortunately be stimulated to attempt a new life-cycle. Moreover considerable evidence exists for the occurrence of ectopic meiosis (heterotypic mitosis) (4, 35, 74, 89, 90, 94).

Direct evocation of more than one embryopotent or diploid totipotent cell within a single trophoblastic blastocyst results in twinning (polyembryony) to which metagenesis is a necessary corollary (51, 68, 76, 83). Benign teratomas (ectopic sexual generation) in the young are most likely identical twins evoked at the same time as their host (72). Identical twins are examples of polyembryony in man. Malignant teratomas (malignant ectopic conceptions) consist of more or less distorted or enmeshed embryonic tissue of a genetic composition different from that of their host (change in genetic composition produced by

meiosis) (61) occurring in a trophoblastic matrix or apposed to it, which matrix has arisen through the activation of a gamete-like cell developed through meiosis from a diploid totipotent cell.

The malignant character of trophoblast has been demonstrated by *in vitro* culture of definitive rabbit embryonic tissue in the presence of its own trophoblast unavoidably introduced with the embryonic tissue (63). In culture the cytotrophoblast infiltrates, erodes, and completely destroys the embryonic tissue (63). Recognized in these experiments as due to release of the trophoblast from the somatic restraint exerted by the entire embryo and mother these results constitute confirmation of previous observations (23). The occasional striking resemblance of phenomena observed in these experiments to chorionepithelioma (63) indicates that trophoblast can exhibit its violently malignant properties with or without assuming the appearance of chorionepithelioma. Because it consists of almost pure trophoblast (cytotrophoblast and syncytium) chorionepithelioma is one of the most malignant forms of cancer. Normally the trophoblast is prevented from overgrowing as chorionepithelioma by a humorally mediated factor produced by the embryo and mother. The question of its identity will be discussed elsewhere.

The occurrence of chorionepithelioma in males, primary in the liver (65) primary in the brain (84) primary in the mediastinum (46 47 52) metastasizing as adenocarcinoma or sarcoma (1 62) and grading by extension into carcinoma or sarcoma (35 82) likewise constitutes evidence not only for the malignant character of trophoblast in the relative absence of its physiological inhibitor normally produced by an embryo and mother (20 63) or male host but at the same time for the existence of somatically dispersed totipotent cells and for somatic response which endows trophoblast with the appearance of carcinoma or sarcoma.

In those malignant teratomas in which the trophoblast is clearly separate from the remainder of the teratoma, it is the trophoblast alone which is responsible for any metastases (37). Destruction of embryonic tissue by

trophoblast has been observed in ovaries: atomas in guinea pigs (55) and confirmed repeatedly (3 24 27 56 57 58). Significant testicular chorionepithelioma or primary chorionepithelioma in the mediastinum or in the brain is identical with primary uterine chorionepithelioma. Since the testes contain a high concentration of totipotent cells normally canalized it is not surprising that occasionally (following meiosis) one becomes activated before spermiogenesis occurs, to form a trophoblast, exhibited in some cases as chorionepithelioma, in others as carcinoma or sarcoma. It is also significant that even the primary carcinomas and sarcomas occurring in testes are known to produce chorionic gonadotropin.

If the trophoblast cell and the cancer are one, the normal trophoblast of pregnancy should be indistinguishable from cancer in some cases at least. By the fresh tissue technique (38) the trophoblast is found to be the only cell indistinguishable from cancer. Moreover in the trophoblastic portion of the cultured rabbit conceptus, the presence is noted of practically all cell types known to be malignant (63). The observation, in a long series of autopsies of pregnant women, that metastases or dispersion of normal pregnant trophoblast may be found in over 80 per cent of the cases is further confirmation of the malignant character of trophoblast (30 75 76). Furthermore when not a part of the normal conceptus of pregnancy trophoblast cells have never been observed except as cancer (1).

Heterologous malignant tumors may be successfully transplanted into the anterior chamber of the eye of animals (40 41 42, 43) whereas attempts to grow heterologous late embryonic and adult somatic tissues have failed. Yet heterologous late trophoblast (human placenta) will grow (53). Therefore heterologous transplantability as a criterion of malignancy is fulfilled by trophoblast.

The human placenta has a somewhat higher rate of aerobic glycolysis than nonplacental tissues. This is not in itself very significant but when the cytotrophoblast and syncytium are peeled from the placenta the ablated trophoblast (chorion) exhibits a high aerobic glycolytic index whereas the residual placenta now

shows the same value as normal somatic tissues (16)

As shown previously the pregnancy trophoblast is the only "normal" tissue known regularly to metastasize (50-79-87). Finally the trophoblast of pregnancy has been observed without any embryo at all, the latter being destroyed at an early stage. In such cases the trophoblast often continues to erode and infiltrate the host. The distinction between such cases and chorionepithelioma is arbitrary (20-9-95).

Morphological multiplicity of malignant tumors is in part a function of the type of tissue in which the ectopic trophoblast develops and of the degree of somatic reactivity or host response manifested by the surrounding cellular elements. This response is fundamentally the same as that which is responsible during gestation for chorion formation and placentation. The combination and relative concentration of trophoblastic and somatic cells determine the architecture and malignancy of each type of malignant tumor. Thus the higher the concentration of trophoblast the higher the malignancy. An anaplastic tumor is one in which the concentration of trophoblast approaches 100 per cent because the relative lack of host response has resulted in little or no investment of the trophoblast by the somatic elements in the vicinity. At the same time the somatic architecture has not been impressed upon the trophoblast. Whereas in pregnancy the chorion is formed following the somatic tissue response of the embryo and mother to the trophoblast, cancer is formed by the tissue response of the postembryonic soma to an ectopic trophoblast.

Somatic response or tissue reactivity forms an extremely complex chapter of morphogenesis and is related to growth stimuli, differentiation and variations in cell form. Variations in cell form in cancer are well known and have been previously described for trophoblast (63). The anaplasia and polymorphism characteristic of Jensen sarcoma when grown *in vitro* are greatly modified in the presence of somatic tissue when the tumor is transplanted *in vivo* (28). A Flexner Jobling tumor transplanted into the rat endometrium produced a decidual reaction (64) resulting in a malignant decidu-

oma paralleling placentation. When rabbit tumors are transplanted into the eyes of alien species variations in parenchymal stromal relations may occur (40). The heterologous transplantation of human carcinomas under similar conditions may be followed by marked histological changes (41). A rabbit squamous cell carcinoma varied histologically according to the tissue into which it was transplanted (43). Chorionepithelioma may grade into sarcoma or carcinoma (34, 81) or metastasize into either (1-62). Moreover the reverse process may take place. Trophoblast syncytium has been observed in cancer of the tongue carcinoma of the breast, sarcoma of the ovary and of course in testicular as well as in uterine chorionepithelioma and in other carcinoma sections (15). It has also been observed that liver metastases from such diverse tumors as mammary cancer hypernephroma and chorionepithelioma may be indistinguishable (33). Somatic response is entirely consistent with the observation that the more nearly a malignant tumor approaches the morphology of the tissue in which it grows the less malignant it is.

Somatic tissue response is well illustrated in cancer of the endocrine glands in which hormone production is associated with the malignant tumor. Cancer of the thyroid for example unless anaplastic, is composed of trophoblast as well as the hormone-secreting cells. These somatic cells are responsible for reproduction in a metastatic lesion of the architecture of the primary growth. Insofar as metastases, or transplants, still contain somatic glandular thyroid tissue, to this extent will such a secondary growth continue to produce thyroid hormone. Metastases or transplants from a primary growth which contains a relatively high concentration of trophoblast cells may be anaplastic thus giving no clue to the primary site. In general, cancer of glandular tissues will not go through many transplants and still produce their characteristic secretions. Cancer of the adrenals ovaries and testes are exceptions. These tumors can be transplanted quite a number of times and still produce hormones. Eventually hormone production may cease owing to the destruction of the somatic secreting cells by the cancer cells. The transport or metastasis of somatic tis-

sue per se is well known although rare. It has been reported for benign hyperplasias. Such metastases are simple autotransplants or autogenous grafts. That they may be transported along with trophoblast is to be expected.

When somatic response or the lack of it results in the rare extragenital chorionepitheliomas or in other highly cellular cancers a strongly positive Aschheim-Zondek reaction may result. Since only the cytotrophoblast produces gonadotropic hormone (96) growths containing a high concentration of cytotrophoblast will produce a pregnancy reaction. Syncytial trophoblast, an adaptation through differentiation of cytotrophoblast to somatic tissue, produces no gonadotropin (96) but sterols instead which are similar to the sex hormones (27 77 96). Syncytial adaptation probably accounts in most cancers for an absence of the pregnancy reaction when performed in the usual manner. However if urine extracts, from persons suffering from cancer are injected parenterally in immature white rats, growth of the endometrium or enlargement of the prostate has been reported to take place after 24 hours (27 77). The urine of nonpregnant cows suffering from carcinoma of the eyes without involvement of the genital organs produces follicle ripening in infantile rabbits (88). This occurs in spite of the fact that pregnant cows give negative Friedman reactions (88). In testicular chorionepithelioma, in addition to very high prolactin titers, gynecomastia, lactation, morning sickness and pregnancy changes in the hypophysis have been reported (26 39 48). In fact practically all testicular cancers produce prolactin, the titer of which is proportional to the histologic similarity of the tumor to chorionepithelioma (36).

It has been reported that the vitamin uniformity of malignant tumors, regardless of tissue origins, manner of induction, sites and animal species, is such as to indicate that cancer forms in effect a common tissue type (73). It has also been pointed out that the metabolic quotients of a wide variety of tumors are nearly the same, that the lactic acid and sugar contents of sarcoma and carcinoma are approximately the same, that enzyme uniformity among tumors is greater than among the same organs in different animals of the same

species, that cytochrome-oxidase activity of a number of tumors is very similar, that in general tumors resemble each other metabolically more than they do normal tissues, or the normal tissues resemble each other (44). It is to be expected that pregnancy trophoblast shares this uniformity with malignant tissue, particularly if they are anaplastic.

The life cycle of antithetic metagenesis is indispensable to an understanding of cancer. Metagenesis explains why trophoblast cannot be embryonic. It explains cancer as a synthesis between two fundamental types of tissues occurring normally in every life cycle: trophoblastic (asexual generation) and somatic (sexual generation) (10 12). Moreover, if cancer is trophoblastic it is clear that it cannot arise from any of the primary germ layers of the embryo (71).

In arthropods and vertebrates where the asexual and sexual generations remain long in intimate contact, metagenesis is distinctly antithetic. In most other forms the definitive two generations develop on the whole without retaining or developing the same close intimacy. As a result pronounced antithesis is generally not observed. It is to be expected, therefore, that cancer will occur most frequently in arthropods and vertebrates (94 93).

In Sauropsida and Ichthyosida, the analogue of the trophoblast is the extraembryonic blastoderm (60 80). With failure of cleavage of an embryopotent cell in Sauropsida the extraembryonic blastoderm proliferates to form a mass of undifferentiated cells called an anidion (60 66 85), a result most likely due to the absence of the primary organizer (66). The cancerous quality of this curious growth has been recognized (85). It is reminiscent of the human trophoblast growing without an embryo (20). In animals, as the sexual generation (embryo) gains ascendancy over the asexual generation (trophoblast) after the critical period during gestation (or incubation), the trophoblast normally degenerates (6). In other words each individual in the course of its life cycle normally destroys the counterpart of cancer.

The development of an ectopic (normally dispersed) totipotent cell into trophoblast rep-

resents an escape from an individuation field in the host through meiotic mitosis. This is the result of the organizer effect of endogenous (54) or exogenous carcinogens raised usually through the localizing effect of a persistent inflammatory process (30) which may be limited to an exceedingly small area to a level of concentration required for the gradual escape of a totipotent cell from the individuation field. The resulting ectopic meiosis, cleavage and formation of trophoblast constitute carcinogenesis. An unsuccessful repetition of the metagenetic life cycle results (10, 11). Almost invariably no adequate embryogenesis follows ectopic trophogenesis and the antithesis of the host alone being insufficient, probably through a lack of an internally secreted inhibitor of trophoblast, the latter maintains its escape from the individuation field. The soma unable to destroy the ectopic trophoblast invests it if possible, thus producing a characteristic more or less malignant tumor.

SUMMARY OF EXPERIMENTS

1. Normal human trophoblast grows readily in the anterior chamber of the eye of the rabbit and is serially transplantable.

It produces chorionic gonadotropin as demonstrated by action on the ovaries of the host and those of a Friedman doe by urine obtained from a transplant bearing male animal.

3. It also produces syncytial sterol hormones as demonstrated upon the uterus of the host and by some degree of inhibition of spermiogenesis in a male host after 60 days.

4. In addition to inflammatory infiltration the presence of giant cells, whirls and strands of syncytium in the iris are suggestive of chorionic invasion.

5. Growth and hormone production of transplanted heterologous trophoblast is now shown in male as well as female animals.

6. This work is being continued.

SUMMARY OF DISCUSSION

Cancer appears to be trophoblastic and develops according to the following sequence:

1. Persistent inflammation associated with high blood titer of carcinogens.

2. Localization and concentration of carcinogenic substances at inflammation site.

3. Meiosis of an ectopic diploid totipotent cell.

4. Formation of a gamete like cell.

5. Activation and cleavage of the gamete like cell is followed with formation of trophoblast.

6. Characteristic malignant neoplasm produced by the somatic response of the tissue where trophogenesis has taken place.

7. Maintenance and growth of tumor because of the lack of a humorally mediated inhibitor of trophoblast.

8. In primary uterine chorionepithelioma factors 1 to 5 are absent or modified by the presence of the trophoblast of the pregnancy conceptus.

9. The affinity of viruses for specific tissues brings about their own localization without a necessary previous inflammation which in fact may characterize the first stages of their invasion.

SIMPLIFIED REPAIR OF THE COMMON DUCT

Use of Umbrella Catheter to Produce Internal Biliary Fistula

J G MONTGOMERY MD F.A.C.S Kansas City Missouri

IN a surgical repair of the common duct in internal biliary fistula may be successfully produced by use of an umbrella catheter. If a dilated vestige of the common duct remains into which the bead of an umbrella catheter may be inserted the entire duct may be reconstructed. The operative procedure is safe, requires less technical skill than other methods, and achieves better results with fewer complications.

In successful repair of the common duct over a rubber tube it is necessary to secure both ends of the tube in such a manner that it will remain in place permanently without the aid of sutures. When properly placed the catheter will not be extruded. We are quite certain from our own investigations that these rubber tubes will last for many years. Biliary obstruction is the only reason for removal. We have found that the new vitallium tubes are too short, must be held in place with sutures, and do not have enough flexibility. In 1943, Bettman and Tannenbaum reported a case in which an incrustated vitallium tube obstructed the common duct and had to be removed.

A new natural rubber umbrella catheter should be used for the reconstruction. The umbrella is inserted through a small stab wound in the bulging proximal end of the common duct to prevent the tube from slipping into the duodenum (Fig. 6). The catheter is then manipulated transduodenally through the opening at the distal end of the common duct if the opening can be found (Fig. 1). If not, the catheter is inserted through a minute stab wound into the duodenum. This stab wound is made small enough to grip the catheter which could obviate the necessity of the customary silk pursestring suture. The catheter extends far enough into the lumen of the duodenum to prevent extrusion that might otherwise occur in postoperative traction due to position of the patient or visceral movements. The duodenum need not be drawn close to the liver as consid-

erable space may be bridged by the tube. All available viscera and fat are used to cover the catheter. Sulfathiazole powder (75 to 150 grains) is sprinkled along the course of repair. Closure is routine with one Penrose drain brought through the abdominal wall.

There is little or no bile drainage and no duodenal fistula occurs in cases repaired in this manner for three reasons: (1) the catheter is fitted securely at both ends and held in place with a silk pursestring suture; (2) there will be no intraductal pressure; the valvular action of the ampulla of Vater is eliminated when the catheter is inserted into the duodenum; and (3) sulfonamide compounds aid in combating infection.

In 1 patient the umbrella catheter has been in place for 3 years (Fig. 7). Whether it is incrustated or not, we do not know. This patient has no symptoms of obstructive jaundice and is normal except for an occasional mild attack of indigestion which may not be due to regurgitation of duodenal contents into the biliary tract. If these mild attacks are due to cholangitis, they are not as serious as attacks of obstructive jaundice or by the recurrence of strictures. The latter two conditions frequently arise in the usual methods of common duct repair and necessitate repeated surgical procedures. The relatively minimal effect of cholangitis has been proved by patients who apparently have been well for many years following cholecystoduodenostomy.

The common duct could not be located in a second case. Only the stubs of the right and left hepatic ducts remained. At operation a stiff T tube was inserted into the hepatic ducts; the catheter portion was introduced into the duodenum as described previously (Fig. 2). This tube slipped free from the ducts into the intestinal tract some time between the eighth and twelfth postoperative weeks. Roentgenologic examination in the eighth week showed the tube in place but on similar

Fig. 1. An umbrella catheter bridges defect in the common duct.

examination in the twelfth postoperative week it was absent. As this patient's condition was good and has remained good, with no symptoms of obstructive jaundice present, it would seem that the internal biliary fistula is functioning properly. This was true when the patient was last checked 14 months after operation. This particular case shows how quickly internal biliary fistulas will form and function. It is apparently true that some internal biliary fistulas (if the tube is not removed or extruded

Fig. 2. A T tube sidetracks the bile from the hepatic ducts into the duodenum.

too early) do function well and are not obstructed by cicatricial contraction. The percentage of internal biliary fistulas that will close by cicatrization is not known. It is likely that the pressure from the flow of bile aids in keeping many fistulas patent.

Many methods of common duct repair have been described. Sullivan in 1909 bridged
